Phosphide of Sodium and its Employment in the Preparation of Phosphorised Bases.—Phosphorus combines energetically with alkaline metals. When phosphorus is thrown on sodium, melted in an iron crucible, placed in a receiver full of carbonic acid, phosphide of sodium is the result; but this body is not definite, and its preparation is dangerous. The following is the method for obtaining a definite compound:—Pour some rectified oil of naphtha or coal oil, boiling at about 120° , into a tubulated retort, furnished with a receiver. Introduce a globule of sodium and a piece of phosphorus, and when the two bodies are melted they combine, producing a glimmering light, and sufficient heat to distil the liquid rapidly. Then the sodium is seen to float, surrounded with black pellicles, which detach themselves and fall to the bottom of the retort. With a glass rod crush this substance, so that it may retain no sodium globules, and the combining process continues. Add the phosphorus, little by little, until there is an excess of it, which will be evidenced by the phosphorus crystallising on the sides of the cooled retort. Treat the phosphide thus formed with sulphide of carbon, and when it is perfectly free from phosphorus dry it in a water-bath in a current of carbonic acid. Black, pulverisable phosphide of sodium is thus obtained.

This compound can be preserved in dry air, but humid

air destroys it promptly. A considerable disengagement of phosphuretted hydrogen results from the contact of water and acids.

Chlorine readily attacks it, transforming it into chloride of sodium and perchloride of phosphorus.

Potassium and calcium behave in the same manner as sodium, and, doubtless, it is the same with the other alkali metals.

Phosphate of sodium placed in a retort in contact with hydriodic ethers speedily transforms them into iodide of sodium and phosphorised radicals.

I have thus obtained the trimethylphosphine and triethylphosphine with their iodides, and that in a quantity sufficiently large to allow me to hope I may complete the study of these interesting bodies.—*Société Chimique de Paris*.

On Some Applications of the Ferrocyanide of Potassium in Chemical Analysis, by EDMUND W. DAVY, A.B., M.B., M.R.I.A., Professor of Agriculture and Agricultural Chemistry to the Royal Dublin Society.¹

I HAVE recently been engaged in making some experiments on the ferrocyanide of potassium or yellow prussiate of potash, with a view to extend its applications in chemical analysis; for though this important salt has already been applied to a number of useful purposes in analytical research, still my experiments have shown me that its use might be advantageously extended, particularly as a re-agent in volumetric analysis, a form of analysis which has of late come into very general adoption, especially for technical purposes, on account of the great quickness, and at the same time, accuracy with which different substances may by its means be determined. The principles upon which volumetric analysis depend are so well known, that I need not refer to them; and though it possesses so many advantages over the older gravimetric method, in which the different substances are determined by weight instead of by volume, it yet has this drawback, that the preparation of the necessary standard solutions often takes considerable time, first, in order to obtain the substance to be used for this purpose in a sufficiently pure and dry state, and secondly, to form a solution of it the exact strength of which may be known: for though it may appear a very simple operation to dissolve a known weight of a certain substance in a given bulk of water or other solvent, yet, when this has to be done with such great precision as is necessary in these cases, it is a tedious and troublesome operation, and any inaccuracy in the graduation of the standard solution will render all determinations made with it more or less inaccurate. It is obvious, therefore, that it would be most desirable that the substances which are intended to be used as re-agents in volumetric analysis should be easily obtained in a pure state, and that where considerable time and trouble have been expended in graduating solutions of those substances, they should not be liable to undergo changes whereby their strength would be more or less altered, but that when standard solutions have once been made, they might be kept and used for a great number of determinations.

The ferrocyanide of potassium fulfils both these conditions; for it is in general met with in commerce almost chemically pure, and in a state in which it can at once be employed as a volumetric re-agent; and if at

¹ From the *Philosophical Magazine*, being part of a paper read before the Royal Dublin Society, December 27, 1860.

any time it should happen to occur not quite so pure, it can readily be purified by re-crystallisation; and, in addition to these important considerations, its solution is not prone to change, especially if it be not left exposed to the action of the light. In this latter respect it has a decided advantage over several of our most useful volumetric re-agents, viz., the permanganate of potash, the protosalts of iron, sulphurous acid, &c., which, from their being so prone to undergo spontaneous decomposition, must be either freshly prepared, or the strength of their solutions accurately ascertained every time they are used, if a day or so has elapsed between each determination.

The employment of the ferrocyanide of potassium as a volumetric re-agent depends on the following circumstances: viz., that it is readily converted into the ferridcyanide of potassium (red prussiate of potash) under different circumstances, and that the point where the whole of the former salt has been changed into the latter may easily be known, either by the use of a diluted solution of a persalt of iron (which gives with a drop of the mixture a blue or green colouration as long as any of the ferrocyanide remains unchanged) or by some other simple indication. Thus, for example, when chlorine is brought in contact with the ferrocyanide of potassium, this change, as is well known, takes place, which is expressed by the following symbols:—

The same occurs, as far as the conversion of the ferrocyanide into ferridcyanide, when an acidified solution of the former salt is brought in contact with a solution of the permanganate of potash, which is instantly decolorized by the reducing action of the ferrocyanide of potassium, which is thereby converted into the ferridcyanide, and this decoloration of the permanganate continues as long as any of the ferrocyanide remains in the mixture.

Again, if a solution of the ferrocyanide of potassium, acidified strongly with either hydrochloric or sulphuric acid, be brought in contact with a solution of the bichromate of potash, the same change of the ferrocyanide into the ferridcyanide immediately takes place.

The first reaction has been long known, and is the means employed at present for obtaining the ferridcyanide or red prussiate of potash for manufacturing and other purposes; the second reaction has been more recently discovered; but I am not aware that the third, in the case of the bichromate, is generally known, or that the changes which occur in the reaction have been previously studied.

From experiments which I made, it would appear that when a solution of ferrocyanide of potassium, acidified with hydrochloric acid, was mixed with one of the bichromate of potash, the following reaction was produced, viz. $6(K_4FeCy_6) + KO_3 + 7HCl = 3(K_3Fe_2Cy_6) + 4KCl + Cr_2Cl_3 + 7HO$; for, amongst other facts, I may observe, that when I mixed together solutions of the two salts in the proportions corresponding to 6 equivalents of the ferrocyanide of potassium to 1 of the bichromate of potash (as indicated in the above formula), acidifying the mixture with hydrochloric acid, I found that the whole of the ferrocyanide was converted into the ferridcyanide, and that any quantity less than that proportion of the bichromate of potash left more or less of the ferrocyanide unchanged. The same results followed the use of sulphuric acid; and it appears that a similar reaction occurs with this acid as with hydrochloric acid, with the exception that in this case

the 4 equivalents of chloride of potassium and the 1 equivalent of sesquichloride of chromium are replaced by 4 equivalents of sulphate of potash and 1 of the sesquisulphate of chromium.

The proportion of either acid used, provided there is enough to strongly acidify the mixture, does not appear to affect the reaction; for I obtained precisely the same results where a very large amount of acid was employed as where the quantity necessary only to strongly acidify the mixture had been added.

On these three reactions which I have noticed, may be based the means of employing the ferrocyanide of potassium in several useful determinations, the first, and one of the most important, of which is the ascertaining the amount of available chlorine in the chloride of lime or bleaching powder, which is a matter of much importance in many of the chemical arts, but particularly in bleaching; for not only does the commercial value of this substance depend on the quantity of available chlorine that it contains, which is subject to great variation from exposure to the air and other causes, but likewise it is of the greatest importance that the bleacher should readily be able to determine from time to time the strength of the bleaching liquor which he employs: for if it be too strong, he knows that the fabric which he bleaches will be injured; and if too weak, it will not be sufficiently bleached, and the process must be repeated, which incurs much additional expenditure of time.

Various methods have from time to time been proposed for the determination of the value of chloride of lime; but the greater number of them, from the trouble required to make the test-solutions, and their not keeping when made, as well as the skill required in their use, render them inapplicable for general purposes.

I shall, therefore, merely refer to the two methods which are chiefly used at present to determine the value of this important substance. The first is Gay-Lussac's, in which the amount of chlorine is ascertained by seeing how much chloride of lime is necessary to convert a given quantity of arsenious into arsenic acid; the second is Otto's, in which protosulphate of iron is substituted for arsenious acid, and the determination of chlorine is made by seeing how much of the bleaching powder is required to change a given weight of the protosulphate of iron into a persalt of that metal: these processes are so well known that I need not describe them.

In both these methods I find that more or less chlorine is always lost, which, however, may be reduced to a minute quantity by very carefully adding the solution of chloride of lime either to that of arsenious acid, or of protosalt of iron; but in ordinary hands they (especially the latter process) will yield results in which too small a proportion of chlorine will be indicated, from the loss of that substance which will invariably take place.

The ferrocyanide of potassium answers admirably for the estimation of available chlorine in the chloride of lime, when used in the manner I shall presently explain, and, according to my experiments, will give in ordinary hands far more accurate results than either Gay-Lussac's or Otto's method. I am aware, indeed, that this salt was proposed by Mr. Mercer some years ago for this purpose; but the way which he recommended it to be used (which consisted in dissolving a certain weight of the ferrocyanide in water, acidifying it, and then adding the solution of bleaching powder from a burette till all the ferrocyanide was converted into ferridcyanide) is, I find, not a good manner of employing the ferrocyanide in this estimation, and, like the other methods, will lead to a loss of

chlorine; for when the solution of chloride of lime is added to the acidified ferrocyanide, a portion of the chlorine is separated, especially if the bleaching liquor be added too quickly, or is not greatly diluted. But the way I propose of using the ferrocyanide of potassium in this important valuation is to mix together a certain quantity of a standard solution of ferrocyanide with a given amount of a graduated solution of the chloride of lime, using more of the former salt than the latter can convert into ferridcyanide; then adding hydrochloric acid to dissolve the precipitate formed and render the mixture strongly acid, and finally ascertain, by means of a standard solution of bichromate of potash, how much of the ferrocyanide remained unconverted into the ferridcyanide by the action of the chlorine of the chloride of lime,—which is effected by adding slowly from a graduated burette the standard solution of bichromate, till a minute drop taken from the well-stirred mixture by means of a glass rod, ceases to give, with a small drop of a very dilute solution of perchloride of iron, placed on a white plate, a blue or greenish colour, but produces instead a yellowish-brown.¹ When this latter effect is observed, it indicates that all the ferrocyanide has been converted into ferridcyanide; and as 147.59 (one equivalent) of bichromate of potash is capable of converting 1267.32 (six equivalents) of crystallised ferrocyanide of potassium into ferridcyanide, and as 422.44 (two equivalents) of the ferrocyanide are converted into the same substance by 35.5 (one equivalent) of chlorine, as is seen by the formulæ already given, knowing the amount of chloride of lime employed, we have all the data necessary to calculate the per-centage of chlorine.

(To be continued.)

TECHNICAL CHEMISTRY.

On the Composition of Cast Iron and Steel, by M. E. FREMY.

I HAVE already shown that iron, cast iron, and steel do not appear to me to be allied, in relation to their composition, as is generally admitted; and it is not correct to say that steel is simply a combination of iron and carbon less carburated than that forming cast iron.

Without absolutely denying the influence exercised by carbon on the properties of steel and cast iron, I purpose nevertheless to show that several other metalloids possess the property of greatly modifying the characteristics of cast iron and steel, and that these bodies do not exist accidentally in these compounds; and that all the uncertainty connected more especially with the manufacture of steel may probably be traced to the action, hitherto little studied, of foreign bodies.

The object of the experiments which I now make known is to determine the conditions under which nitrogen can combine with iron.

Every chemist is aware that to M. Despréztz we owe the important discovery of nitride of iron; to him we owe the demonstration that iron, at red heat, decomposes ammoniacal gas, fixes the nitrogen, becoming itself white and brittle, and augmenting in weight, sometimes to the extent of 11.5 per cent. Submitted to the action

of acids, this body produces a salt of iron and an ammoniacal compound.

These clear results have, however, been doubted by some chemists. Some have thought the increase in the metal's weight was owing to an oxidation produced by the water or air which ammoniacal gas is capable of retaining; others, that the modifications of the physical properties of the iron were due to an alternate phenomenon of the oxidation of the metal and the reduction of the oxide by the hydrogen of the ammonia.

Though convinced that the experiments of M. Despréztz have no need of confirmation, I wished, however, to repeat the contested experiments in eliminating all sources of error which could arise from impurity in the ammonia or the humidity of the gas. I feel it incumbent upon me to state that every trial has completely confirmed M. Despréztz's position. In numerous experiments I have invariably seen red-hot iron decompose ammoniacal gas, producing the brilliant white body called "nitride of iron" by M. Despréztz.

The opinion has been advanced that the product of the decomposition of ammonia by iron might be a combination of metal with a hydride of nitrogen less hydrogenated than ammonia.

This question must be decided by experience. In fact, under the influence of oxygen, the compound studied by M. Despréztz produces peroxide of iron. In conducting this decomposition in a porcelain tube, communicating with the tubes designed to fix the water produced by the reaction, it is easy to distinguish whether the compound was a nitride or an amide of iron.

This experiment has been made with the greatest care. A known weight of the nitrogen compound was made red-hot in a current of oxygen, the metal was transformed into pure peroxide of iron, nitrogen was disengaged, and the tubes for absorbing the water underwent no alteration in weight. This experiment appears to me conclusive, and proves that the body produced by the action of ammoniacal gas on iron is actually nitride of iron, and that it contains no hydrogen.

This essential point being once established, it became necessary to determine under what other circumstances iron would combine with nitrogen.

I have first examined the action of pure nitrogen on metallic iron. The nitrogen was obtained either by decomposing nitrite of ammonia, or by the action of copper on atmospheric air, and the gas was purified and dried by the most efficacious means. It results from these experiments that nitrogen combines with great difficulty with the iron prepared by the processes usually employed in manufacture, but that it unites with the metal when presented to it in a nascent state. Thus, I have obtained nitrogenised iron by making nitrogen impinge on the oxide of iron at the moment of its reduction by either hydrogen or charcoal.

Cyanogen also modifies the properties of iron; but I have reserved the study of this reaction for another paper, to be devoted to the study of the phenomena resulting from the combined action of nitrogen and carbon on iron.

The processes to which I am about to refer doubtless yield nitride of iron, but the reactions are slow and incomplete. Thus, completely to nitrogenise small fragments of iron wire by ammonia, I have been obliged to pass the current of gas over the red-hot metal for three entire days.

In order to submit nitride of iron to a thorough chemical examination, and, above all, to study what influence this body is capable of exercising on the con-

¹ The yellowish-brown colouration which is at first produced when enough of the bichromate has been added, quickly changes to a greenish colour by some secondary reactions which take place when the persalt of iron is left in contact with the mixture. But this does not interfere with the test; for it is the first effect which is produced which indicates the completion of the reaction, and not the after changes which may result.

stitution and properties of steel, I have been obliged to devise a new method, which enables me to prepare this metallic nitride with facility. I have been so fortunate as to arrive at this result by decomposing at red heat protochloride of iron by dry ammoniacal gas. I introduced into a porcelain tube about 200 grammes of anhydrous protochloride of iron. This tube I made red-hot, and passed over the salt a current of ammoniacal gas, furnished by ordinary liquid ammonia, slightly heated, the gas being dried by passing through long tubes filled with caustic potash.

Under the influence of ammoniacal gas the metallic chloride decomposes rapidly; chloride of ammonium and a curious amide salt are disengaged. This salt is instantly decomposed by water, producing ammonia and oxide of iron. After the operation an inflated and partly melted mass is found in the tube; it is sometimes gray and often also metallic, white, and brilliant. This body is nitride of iron.

I submit to the inspection of the Academy about 200 grammes of nitride of iron obtained in this way. This body, till now hardly known to chemists, can henceforth be prepared with the greatest facility. It will, I have no doubt, become a new and valuable adjunct to our researches, by furnishing nitrogen to mineral substances or organic bodies. This process for the production of nitride of iron applies to the preparation of other metallic nitrides. By the same method I have obtained combinations of nitrogen with the metals of the iron group. A special paper will be devoted to these compounds.

I have proved that nitride of iron, proceeding from the decomposition of protochloride of iron by ammoniacal gas, possesses all the properties of that obtained by passing ammoniacal gas on red-hot iron.

This nitride is easily reduced to powder; it is less oxidisable than pure iron; it is very slowly attacked by nitric acid, but very speedily by sulphuric and by hydrochloric acids.

Nitride of iron when dissolved in acids produces ammoniacal and ferruginous salts.

According to the experiments made at my request by M. E. Becquerel, nitride of iron becomes magnetised readily and permanently like steel, only this property appears less developed than in ordinary steel.

Nitride of iron is remarkable for its fixity, and, in this respect, is allied to nitride of titanium, which has been so carefully studied by MM. Wöhler and H. Deville; in fact, it may be made red-hot without undergoing decomposition. Oxygen attacks it only at a high temperature, and then transforms it into peroxide of iron.

Nitride of iron, when heated in a charcoal fire, undergoes an important modification, to which I must revert when treating of the chemical constitution of steel. It is transformed, in this case, into a metallic mass analogous to steel, and, like it, becoming very hard by tempering. If nitrogen is present in this new compound it does not exist in the same state as in nitride of iron; for when the hardened product is heated in a hydrogen current no trace of ammonia is disengaged.

The most remarkable reaction of nitride of iron is that which it exercises on hydrogen. When slightly heated in this gas it decomposes immediately, yielding ammonia, and leaving a residue of pure iron.

This direct combination of hydrogen with the nitrogen contained in a metallic nitride appears to me a very curious fact. It, however, proves that nitride of iron can be employed to yield nitrogen to other compounds. The easy decomposition of nitride of iron by dry

hydrogen has enabled me to determine the different circumstances in which iron can unite with nitrogen. This experiment, in fact, removes all doubt.

It would be otherwise were the nitride attacked by an acid and the liquid then decomposed by potash. Reagents, and especially potash, often contain nitrates which, under the influence of protoxide of iron, produce ammonia.

The action also of hydrogen on nitride of iron has enabled me to analyse this compound readily. To determine the composition of nitride of iron it is necessary only to estimate the loss this body undergoes when heated in dry hydrogen.

It results from my analyses that nitride of iron obtained by means of protochloride of iron contains 9.3 per cent. of nitrogen, this composition corresponding to a nitride represented by the formula Fe_3N . By making ammoniacal gas react on iron, M. Despréts has proved that the weight of the metal augments sometimes as much as 11.5 per cent.; the nitride formed in this case would be represented by Fe_2N .

I shall not now dwell upon the formula of nitride of iron, for there is no proof that this compound has yet been obtained in a state of absolute purity; the temperature at which it is formed, and the hydrogen atmosphere then surrounding it are capable of varying its composition. It is, however, to be presumed that iron can unite with nitrogen in several proportions, as is shown by the following experiment:—Submit to the action of ammoniacal gas for twenty hours some small, red-hot cylinders of pure iron, sufficiently large to render the chemical action incomplete, and the weight of the metal, under these circumstances, does not augment more than 6 per cent.

After this experiment, the metallic cylinders, when examined, will be found to be composed of two very different parts: the external one almost melted, exceedingly friable, and may be detached by the slightest blow; the other, internal, rather hard, and still metallic. The external part is formed of 9.8 per cent. of nitrogen and 90.2 per cent. of iron, corresponding to the formula Fe_3N . Thus, the nitride produced by the action of ammoniacal gas in excess on iron has the same composition as that resulting from the decomposition of protochloride of iron by ammonia. The internal and still metallic portion can be cut by a file; it is, nevertheless, very brittle and contains nitrogen, but in much smaller proportion than the preceding. It presents in its general aspect a certain analogy with metal called in the foundries burnt iron.

It would be a curious circumstance to ascertain whether this accident of its manufacture which deprives iron of all its useful properties is not owing to a combination of iron and nitrogen. This is a point not to be neglected in my future researches.

Such are the new facts relative to the history of nitride of iron which I wish to make known to the Academy. I will sum them up in a few words:—

1. The object of my first experiments was to reproduce and prove the exactness of the experiments M. Despréts has described in his paper on nitride of iron.
2. I then established the fact that the body produced by the re-action of ammoniacal gas on red-hot iron is really nitride of iron and not of amidide: it contains no hydrogen.
3. It results from my experiments that the direct combination of nitrogen and iron takes place chiefly when the metal is in a nascent state.
4. I have proved that nitride of iron is formed with

the greatest facility by decomposing anhydrous protochloride of iron by ammoniacal gas. This method applies to the preparation of other metallic nitrides.

5. The composition of nitride of iron prepared by the action of ammoniacal gas either on iron or on protochloride of iron, is the same; it contains about 9.5 per cent. of nitrogen, and may be represented by the formula Fe_3N .

6. Nitride of iron is completely modified when heated in a charcoal fire; is no longer decomposed by hydrogen; and appears to resemble steel.

In another Memoir I shall ascertain whether nitride of iron can be employed in the preparation of steel.—*Comptes-Rendus*.

PHARMACY, TOXICOLOGY, &c.

'Supposed Case of Poisoning.'

THAT medical men are sometimes extremely rash in expressing opinions, even when they involve a charge of murder, is a fact unfortunately too well known to need additional illustration. A case, however, has just occurred at Cheltenham to which we feel bound to allude, not only on account of the want of chemical knowledge and skill displayed, but because it serves to justify the opinion we expressed a short time ago that the generality of medical men are not possessed of the necessary qualifications for the office of public analysts. We may relate the case, as we find it detailed in the *Cheltenham Chronicle*, in a few words. An illegitimate child died rather suddenly in the Cheltenham Workhouse, and a post-mortem examination of the body was made by the medical officers. The stomach was found perforated, and the mucous membrane was of a dark colour, with a few minute white spots upon its surface. This was held to be occasioned by arsenic, and accordingly an inquest was held, at which the following evidence (which we, of course, condense) was given:—

Dr. BIRD, of Cheltenham, said he took some mucus from the duodenum and stomach, mixed it with distilled water and hydrochloric acid, and boiled a piece of clean copper wire in the mixture. The copper wire became coated with an arsenical deposit. He next cut portions of the stomach, colon, and duodenum into small pieces, and boiled these with distilled water and potash. He then added some hydrochloric acid, and boiled this mixture with another piece of copper wire, which also showed the presence of arsenic. He then took a portion of the same fluid, and added some ammonio-sulphate of copper, which gave a bright green colour. To another portion of the same fluid he added ammonio-nitrate of silver, which gave a precipitate of a "slight lemon-yellow colour." He then boiled another portion of the duodenum with water and hydrochloric acid, and placed in the mixture a piece of bright copper wire, which quickly became coated with a white coating, indicating arsenic. After drying the wire he placed it in a tube, and on heating the tube the smell of arsenic was very distinct. The Doctor added that he had no hesitation in saying that the stomach contained a quantity of arsenic.

Mr. ALFRED SANDERS, surgeon, said he had tested a piece of the stomach by Reinsch's test, and the copper soon became covered with a coating of arsenic. He also tried other tests, all of which gave unmistakable evidences of the presence of arsenic. He had not the

slightest doubt that the body contained a quantity of arsenic.

At this stage of the proceedings a gentleman suggested that some portions of the stomach which remained should be handed to a competent analytical chemist and the inquest adjourned. The Coroner assented, and the remains were placed in the hands of Mr. Horsley, the recently-appointed analyst at Cheltenham. When the inquest was resumed, Mr. Horsley detailed the experiments he had made, all of which went to prove that not a trace of arsenic was discoverable in any of the matters handed over to him. Upon this Dr. Bird and Mr. Sanders recalled the evidence they had previously given, and expressed themselves perfectly satisfied that no arsenic was present in the body, and that the child died from natural causes.

It would be a waste of space to comment at any length upon Dr. Bird's evidence, so manifestly absurd is it to the merest tyro in chemical and toxicological science. The idea of adding ammoniated sulphate of copper in a trial for arsenic to hydrochloric acid and potash (we are not told which was in excess), and, still worse, adding nitrate of silver to some of the same fluid, would never have occurred to any one having the smallest knowledge of chemistry. We may point out, however, one source of error which might possibly have serious consequences when a medical man without special means sets about testing for arsenic. The hydrochloric acid ordinarily supplied to surgeons and pharmacists is notoriously contaminated with the poison. We saw recently a specimen in use in the dispensary of one of our large metropolitan hospitals, which contained nearly 0.1 of a grain per cent. Common sulphuric acid also contains it, and in this case Mr. Sanders ingeniously confessed that, supposing he really did find arsenic, he might have added it himself from this very source, although we are not told how he used the sulphuric acid in Reinsch's test. The remainder of the evidence of these gentlemen we may leave with all its absurdities, only remarking that copper boiled with animal matters almost invariably suffers some change of colour, which by an inexperienced man may be taken for a metallic deposit, and that the apparent sublimate which Dr. Bird procured was no doubt due to his neglect of the common precaution of washing his copper with ether to free it from fatty matter, which always adheres.

Mr. Horsley's evidence calls for no remark, except to point out his error of ascribing the method of detecting arsenic by distilling off the chloride to Dr. Taylor, when it has been shown to belong exclusively to Dr. Odling. In a general examination we think Mr. Horsley would be needlessly inconvenienced by precipitating the antimony with tannin; but as in this case his attention was solely directed to the detection of arsenic, it was of no moment.

In conclusion, we can only express a hope that medical men will abstain from undertaking examinations of this kind, and in all cases hand the suspected matter over to those who are specially qualified for the task. Such mistakes as that reported generally entail a severe penalty on the perpetrators by the want of confidence which they inspire; but when we reflect on the possible consequences to the unfortunate mother in this case—with already one sin to answer for before a world which has little charity—if Dr. Bird's and Mr. Sanders' evidence had passed uncontradicted, we cannot help thinking that the formal censure of a coroner's jury is but a small punishment for "originating a charge of so serious a nature, and which had no foundation in fact."

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Two Lectures on Musical Acoustics, and on the Physiological and Psychological Causes of Musical Harmony and Discord, by Professor HERMANN L. F. HELMHOLTZ, of Heidelberg.

LECTURE I.

In the Lectures which I shall have the honour of delivering before you I will try to explain why there is difference between consonant musical intervals and dissonant intervals. The law which rules this difference has been known, partially, at least, for a long time. The old Greek musicians knew what was the proportionate length of strings of the same materials, make, and tension, adapted for giving consonant intervals. The discovery of this law is ascribed to Pythagoras. He found out that if you wish to get the octave of the sound which any string gives, you must shorten the string to half its length; if you wish to get the fifth of the fundamental sound of the string you must shorten the string so that its length becomes two-thirds of the former length, and so on.

The Greek musicians knew this law only in relation to strings. The modern natural philosophers found out that if the nature and tension of the strings are alike, the length of a string is in inverse proportion to the number of vibrations. They, therefore, found out the real cause of this law, which was at first adopted for strings. They concluded from the old Greek law of consonance that there was a definite proportion and a simple proportion of the numbers of vibrations between two sounds which give consonantal intervals. The sound of the higher octave is produced by twice as many vibrations as the lower octave, or fundamental sound. A sound which is higher by one-fifth makes three vibrations in the same time where the fundamental sound makes two vibrations. A sound which is higher by one-fourth makes four vibrations in the same time that the fundamental sound makes three vibrations; and in the same proportion for the major fifth and minor third. In this way the proportions for all simple consonant musical intervals can be given by the first six numbers of the series of the whole numbers. This is a curious law. We do not understand at first what the series of the whole numbers has to do with the consonantal intervals. But you see also that this law is a fundamental law for the whole construction of the musical scale, for the musical scale must contain those consonant intervals; and, therefore, the series of sounds which are used in our musical scale is given by these proportions of the whole numbers. There has been much discussion about this law. Several natural philosophers have tried to find an explanation of it. The common hypothesis was that the human soul found a peculiar pleasure in simple ratios and a dislike of complex ratios, —ratios which could not be expressed by the simple number. But you see this explanation is no explanation at all; because it may be, if you have not studied natural philosophy, you do not know that a sound is produced by vibrations, you do not know that higher sounds have therefore more vibrations in the same time than lower sounds, and you do not know anything about these simple proportions of consonant intervals. Therefore this explanation cannot be considered as sufficient, and I will try in these Lectures to describe those physiological and psychological phenomena which explain this fundamental law of the musical scale.

In this first Lecture I will explain the different qualities, the physical differences in the sound, and the physiological functions and faculties of the human ear, which are necessary for distinguishing and perceiving those differences of sound which are really distinguished and perceived. I

will suppose that all of you know by common experience that every sound is produced by the vibrating movement of the air, or by the vibrating motion of any elastic body by which sound is transported by the air to the ear. In many cases you can see these vibrations, if they are vibrations of solid elastic bodies; in other cases you can, if the sounds are strong enough, feel the vibrations of the air; this refers principally to the vibrations of the lower sounds, which are the most easily felt.

These vibrations are produced, as you know, in many different ways. The common law for the production of musical sounds is that the motion of the air which is performed during every single vibration is repeated regularly a great number of times. We distinguish, as you know, between such sounds as are called noises and musical sounds. The motion of the air which corresponds to noise may be quite regular, but in such cases there is no regular repetition of the same motion. In musical sounds we have a regular repetition of the motion which was executed during the first vibration; this motion is repeated in equal periods of time, and quite in the same way. That constitutes the principal and fundamental difference between a musical sound and a regular sound or noise. Therefore, the motion of the air which corresponds to musical sounds is commonly a motion which goes backward and forward; it is not constant and continuous, but a vibrating and oscillating motion.

These oscillations of the air, and of all elastic bodies, are produced in different musical instruments in very different ways. You have, first, instruments constructed with strings, as the monochord, the piano, the harp, the guitar, or the violin. In those instruments a certain string is moved and put into vibration, and the vibrations of such a string continue during a certain time, and give regular shakes to the ends of the string, which are fastened upon the sounding-board, and from thence transmitted by the air to the ear. In other cases you have vibrations of the air produced, as in organ pipes. A thin current of air is moved against the lip of the pipe and there broken, and by this breaking the vibrations are produced. In other cases you have elastic plates, which alternately open and close apertures for the air. In this way all reed pipes are constructed, the air is blown into a box with openings. An elastic plate closes the openings, and when vibrating sometimes opens the hole by which the air escapes, and then closes it again, so that the current of air is interrupted, and becomes separated into single pulses of air. In this way the sound is produced in the harmonium, the reed pipes of the organ, the oboes, the clarionets, and so on. In the trumpet there is a similar mode of interrupting the current of the air, which comes out of the mouth by the lips, which are vibrating themselves, so that they close and open the mouth, and the current of the air coming in small pulses into the instrument, the sound is strengthened by its resonance.

So you see that the manner in which such vibrations of the air are produced is very different, and, indeed, the form of the motion of the air itself which is produced by these different musical instruments, is itself very different. For explaining these facts which I have brought before you we have a very convenient instrument called a siren. A siren in its simple form is composed of a brass box into which air is blown from beneath. The covering of this box is perforated by a series of holes; and above this covering a brass disc is rotating, which has a corresponding series of holes. [In explanation, the Lecturer exhibited two cardboard discs perforated with corresponding holes at regular distances; so that when the one disc rotated the holes in both would be alternately opened and closed.] If you move the upper disc slightly the box will be closed and the current of air passing out is interrupted; moving it a little further you have again the opening. If the motion is very swift we can have a great number of interruptions to the current of air during a very small time, by

which it is divided into single pulses which give the vibrations to the outer air,—these are transported to the ear, and you hear the sound. Now I will use a more complicated instrument. In this one [pointing] the disc and the covering of the box have four series of holes; the interior series has eight openings, and the exterior one has sixteen openings. Then you see that if the disc turns, in a given time the interior series or holes will give eight vibrations to the air during the time of one revolution of the disc, and the exterior series of holes will give sixteen revolutions, and therefore will give the higher octave. And you see that in this case the number of pulses which the air receives from the instrument are fixed by the number of the holes, so that the proportion between the sounds which correspond to the different series of these holes, corresponds exactly and accurately to whole numbers. In this more complicated instrument I have two such boxes, and two discs. You cannot see the discs as you have seen in the other instrument, because I have put some resounding boxes above the discs that they may give a better quality of sound. There is another peculiarity in the construction of this instrument. I can turn by this axis [pointing] the upper box so that it rotates itself. And by this rotation the number of the pulses of air can be altered a little. You see if the disc turns in one direction and the box itself turns in the opposite direction, then because the holes go in an opposite direction they will reach each other more swiftly than they do if the box is reposing. And if I move the box in the same direction as the discs are revolving they will not reach each other with quite so much rapidity. So I can get small alterations of the tone, and can alter the pitch of the higher box a little. [The Lecturer proceeded to make the experiment; the air being forced into the siren by a pair of bellows.]

I make this experiment principally to show you that the consonant intervals correspond quite accurately to these simple proportions of the vibrations. I can alter the pitch; I can get consonant tones by the apparatus, and the proportion of the whole numbers is kept quite accurately as long as our box is standing. As soon as I move it the pitch is altered, and you will hear the alteration of the consonance. [Experiment.] You hear that the sounds become higher and higher as the velocity of the revolving discs is increased by the effort of the current of air. Now, opening the series of twelve holes, we get a fundamental note. Opening in the same box the series of eighteen holes, we get the fifth, a perfect fifth going on quite continuously and without roughness. Taking the fundamental note again, and shifting the box in the manner I have described, you can perceive the alteration in tone, higher and lower, by this means I can alter the tone in a very small degree. The proportion between the sounds is given and fixed by the number of holes in these boxes which number cannot be altered. You heard the sound become higher at first by the increased velocity of the disc and by the increased number of vibrations. Then I obtained the pure and actual consonants by these intervals, and you saw that if I moved the upper box so that I altered the higher tone by a very small amount, then the consonance was damaged, it was neither so good nor so beautiful as before.

Now, with regard to the differences of the sounds, the first thing we have to speak on is the intensity of the sound. The intensity of the sound depends on the amplitude of the vibrations. If we cause a string or any elastic body to vibrate slowly, we have sound of small intensity; if we make the vibrations more rapid, then we have a sound of greater intensity. Therefore, the amplitude of the vibrations corresponds with the intensity of the sound. Then we have to distinguish the pitch of the sound. I have just said that the pitch depends only on the number of the vibrations made during a certain time, and we express it by the number of vibrations made during one second. The lowest sounds are produced by the fewest

vibrations, and the lowest number of vibrations which we can hear as real musical sounds, is about thirteen or fourteen in the second. It was erroneous, as stated by some one, that sound could be produced by eight vibrations in the second, and that it was wrong as afterwards shown by Despréts. Those tones of thirty vibrations have no good musical body, one begins to hear the single beats. Good musical sound is only produced by forty vibrations in the second. This corresponds to the lowest *F* on the piano. Those of you who play that instrument will know that the lowest notes are too low to give the ear the good impression of a musical sound. This depends not upon the construction of the instrument; it is the same with the lowest sounds of organs and all other instruments. The makers only go down to the sound of forty vibrations on the violoncello and basso. We can go to an extremely high number of vibrations to produce high tones. In the scale which we commonly use for music, as for example, the compass of the piano-forte, the highest note corresponds to nearly 4000 vibrations. But we can get higher sounds still by small tuning-forks, and Despréts found out that he could get sounds of 30,000 vibrations or more by their use. But if you go only a small interval beyond the limits of the piano, then these sounds become very disagreeable and their musical pitch is not very distinct. You can hear that they become higher and higher, and it is very difficult to say whether they become higher by an octave or a fifth and so on, and therefore they cannot well be used in music.

The next difference is in the *quantity* of sound. You know that the same note formed by the violin or the trumpet or the human voice has quite a different quality of sound. The French call this the *timbre*. Now, this difference of the quality must depend on the form of the vibrations. We have seen that the amplitude of the vibrations corresponds to the intensity of the sound; that the number of the vibrations corresponds to the pitch; therefore there remains nothing else than the form of the vibrations for explaining the different quality of sounds.

And, indeed, the form of the vibrations can be extremely different even if we take such a simple instrument as a single string. For showing this I have fastened before the black board a string, the motions of which are the same as those of a musical string, only slower; and I will show you the different forms of motion which such a string can produce. At first I can move the string in such a way that every point of it moves according to the same law, moves in the same way as the point of the pendulum would move if the pendulum was put into vibration. This motion [causing the string to vibrate] would give a very soft and simple sound. Then I can strike the string in the same way as it is done in the piano, and you perceive the wave runs up and down along the string. In giving it the motion it would have in the guitar or in the harp, I draw it to the side and let it go when you see the motion of the waves. Then I can put the string in another kind of motion, which is the motion it receives on a violin. There, one end of the string is going slowly across, and it falls down with great velocity, and the other end of the string goes down slowly and jumps up swiftly.

We know that if we excite the same string by striking against it, or by drawing it up with the finger or with the violin bow, we have always the same musical sound; but the sound is different as to its quality. Therefore, we see that it is necessary to consider the form of motion given to elastic vibrating bodies to find out on what the quality of the sound depends. That is the main subject on which we have to treat. Now, the number of forms in which a string can vibrate is infinitely great; but however complicated they are, we can consider them as a sum of motions of a very similar kind. Mathematicians distinguish a sort of vibration which they call simple vibrations, or you may also call them pendulum vibrations, because every point

of the string moves according to the same law which rules the motion of the pendulum. Such a string as we have here can execute very different pendulum or simple vibrations. Vibrations in which every point of the string does not move according to the law of the pendulum we may call complex vibrations. [The Lecturer proceeded to show the different forms of simple and complex vibrations that could be produced from a single slack wire.] If I touch any point of the monochord string with the hairs of a painting-brush, that point is obliged to repose; and when I strike the string, the sound beyond that point ceases, and is abolished by the friction of the hairs. The number of vibrations of these simple sounds of the string is very different. You saw that I could bring the string into different forms of vibration by altering the mode of striking it and the position in which it was struck. When the string is divided into two parts it has twice as many vibrations as before, when it is divided into three parts it has three times as many, and so on. And in this way we get a number of sounds which can be given by the same string. If I touch one part of the string with the brush and then strike it, you hear the sound, and I would have you observe that I can take away the brush after I have excited the string without altering the sound. Now, such vibrations of the string can be compound; one string can execute two such systems of motions in the same time. As, for instance, I can move this string as before, so that it makes simple vibrations, and whilst it is doing so I can strike it in the centre and it will have the up and down motion combined with the first swinging motion. In this way I can combine two systems of simple vibrations. You may compare the motions of the string with the waves on the surface of water. If you look down on to the sea from any high point of view you will commonly see long systems of straight waves coming on from the horizon to the shore; then they are reflected from the shore, and go back into another direction. You may throw a stone into the water, and you will have the circular waves going out from the point where the stone fell down and spread over the wavy surface, quite in the same way as they would spread on the plain surface of reposing water. If you consider this, you see that the circular waves are added to the wavy surface in the same way as to the plain surface. Every point of surface, indeed, becomes as high as the same circular movement of the same plain waves would make, and if you consider the points between the waves as the level, then you may see that the height of every point of the surface above the level is like the sum of the heights, which would be brought on by the single systems of waves. Now, in the same way the vibrations can be composed on the string. If we execute such different kinds of such composition of vibrations then we can bring forth and produce every possible form of vibration. And every form of vibration of the string which is possible can be composed by such simple vibrations only in one way. I have a diagram here to explain this. The first waves are such forms of the string as would be made by simple vibrations. Beneath you have the second simple vibration given by the red line. If you put all the heights of this curve above the other you get the black curve there above which is composed. To that black curve, which is represented in the lowest diagram as a green line, the third vibration is added, and you see the black line is as high above the green line as the red line is above the black line in the second diagram. In this way we get the second black curve, and by putting together those vibrations we get the red at the bottom. The vibrations can also be shown by the aid of the electric light. Here the electric light is reflected by a little mirror on one of the points of the branches of this tuning-fork [pointing] on to the screen. If the tuning-fork is put into vibration then its vibrations are reflected on to the screen, but in a very increased manner. [The Lecturer proceeded to show the vibrations by the aid of the electric light and

be screen. He first showed the vibrations of a large tuning-fork producing fewer vibrations, and then of one

an octave higher. He then reflected the vibrations from both tuning-forks at the same time producing a composed system of vibrations.] There are a great variety of forms, and if we take a number of simple oscillations it is possible to get every possible form of composed vibrations.

Now, we have seen that a great number of simple vibrations can exist together on the surface of water. They can exist together in the same way in a room filled with air; as, for instance, if you take a room where a dancing party goes on, there you have the sounds of instruments, the sounds of voices, the rustling of dresses, and so on. You have a great number of sounds which are confused altogether in the same mass of air, but you can perceive them all separately. Even by your ear you can perceive that all these sounds co-exist at the same time in the same place. Now, the motion of the air in such a room must be a very complicated one. You must suppose that from the mouths of the gentlemen there are going out waves of the length of four to eight feet, and from the mouths of the ladies waves of the length of two to four feet. Then the rustling of the dresses and silk gives a little crisping in the air, like the crisping on the water produced by the wind blowing on its surface. These air-waves are reflected by the walls, return and pass through each other, and although the whole system is so complicated, the human ear can distinguish all the single sounds which are combined. This is a very wonderful fact; but more so because the ear distinguishes the sounds under difficult circumstances. If you look down upon the water you see the whole surface at the same time,—you overlook the whole of the system,—and you can see the motion and compare the motion of all parts of the surface. But if you hear the sounds in a room you can perceive only the motion of that air which is next to your ear, you perceive only the motion of a single point in the whole mass. It would correspond to what would happen if, instead of looking on the water itself, you put a stick on the surface, so that the stick would be moved, and only watched the motions of the stick. If you did that, I do not believe you would be able to separate them to the single systems of waves which go and come to this point. Therefore this separation of different undulations is far more difficult to the ear than the same is to the eye. Now, we have seen that the ear separates such a mass of sound co-existing in the room, which is really composed by different voices and instruments. But if it composes such a mass of sound, it must also analyse sounds which are not composed, from their original source; because every quantity can be considered

as the sum of parts. The number five can be considered as the sum of three and two, or as the sum of three and one and one, and so on. So, as there exists such a number of sounds produced really by different instruments, the ear can also decompose sounds into their simple elements. So, for instance, we have seen the motion of the string can be considered as a composition of different oscillations. We can distinguish these simple oscillations also by the ear. If you listen, I will first touch the string with the brush, so that we have only the second harmonic of the string. If I cause the fundamental sound to come out, you will hear the harmonic and the fundamental sound, and at last you will have the natural sound of the string. So much about the compositions of the musical sounds. In the next Lecture I will try to make the application.

CORRESPONDENCE.

Adulterated Milk of Sulphur.

To the Editor of the CHEMICAL NEWS.

SIR,—A friend of mine recently handed over to me a small quantity of Milk of Sulphur which he more than suspected had been "doctored."

I submitted it to heat in a covered crucible, and was surprised to find that only 48.92 per cent. of sulphur was driven off, leaving 51.08 per cent. of a white pulverulent substance, which, on analysis, proved to be sulphate of lime. An instance of this sort needs no comment, and the fact that it was sold at 1½d. per oz. and only costs to the shopkeepers about 3d. per lb. does not improve it.

By publishing this, you may lead people to be on the look out when purchasing it for the future.—I am, &c.

W. CROSLBY, Analytical Chemist.

Ormesby Iron Works, Middlesbrough on Tees.

P.S. I send you a sample in the very paper in which I received it.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Action of Sulphurous Acid on Metals and Metallic Oxides at High Temperatures.—Schiff records (*Annal. der Chem. und Pharm.*, bd. cxvii. s. 392) the following results of his experiments with sulphurous acid and some of the metals and metallic oxides at high temperatures:—

Cupric oxide when heated in the dry acid is only partially changed to cuprous oxide; a third of it passes into sulphate of cupric oxide: $3\text{Cu}_2\text{O}_2 + \text{S}_2\text{O}_4 = \text{S}_2\text{Cu}_2\text{O}_8 + 2\text{Cu}_2\text{O}$.

Zinc Oxide undergoes no alteration.

Lead Oxide.—The greater part is changed into sulphide, and some into lead sulphate. Quantitative analysis of the products gave widely different results. The carbonate of lead behaves like the oxide.

Tungstic acid could only be reduced to the blue compound of tungstic acid and tungstic oxide.

Iron (finely divided) undergoes combustion more or less actively even at a low temperature, and forms sulphide and a small amount of sulphate of the protoxide.

Lead (precipitated from the acetate by means of zinc) does not undergo combustion, but by longer action is changed mostly into the sulphide.

Tin (reduced from the chloride by zinc) undergoes active combustion below the melting-point, and the metal is changed into a yellowish mass, which is a mixture of stannic oxide and bisulphide. If this product is heated in the sulphurous acid until the stannic oxide becomes insoluble in dilute acid, the bisulphide may be extracted.

Antimony is attacked with difficulty: it is converted to the red amorphous sulphide.

Arsenicum is only acted on by sulphurous acid when in the form of vapour, and then but slowly. Two sublimate are obtained; that nearest to the heat is in most part sulphide of arsenic, the furthest is arsenious acid. Both have some sublimed arsenicum with them.

Metallic copper, mercury, and bismuth undergo no change.

Potassium burns rapidly when heated in sulphurous acid, and leaves a yellow residuum which contains little or no sulphurous acid, but consists of sulphate, hypsulphite, and polysulphuret of potassium—the last being the principal ingredient.

II. ORGANIC CHEMISTRY.

Compounds of Sesquistannethyl.—These—a very short notice of which, by Cahours, appeared in the CHEMICAL NEWS, Vol. i. p. 157,—have been further investigated by Kulmiz (*Journal für Prakt. Chem.*, bd. lxxx. p. 60), who describes more minutely the salts of this radical.

Chloride of Sesquistannethyl is prepared from the sulphate by the addition of the chloride of barium; the bromide by the action of hydrobromic acid on the hydrated oxide of sesquistannethyl. The iodide may be prepared either by acting on the sulphate of sesquistannethyl by iodide of potassium, or by treating an alcoholic solution of the oxide with iodine. It forms a clear mobile liquid, which has a very irritating odour; it boils between 180° and 200°, and has the specific gravity 1.850.

Sulphide of Sesquistannethyl.—Sulphuretted hydrogen is passed to excess through one-half of an alcoholic solution of oxide of sesquistannethyl; the excess of HS is then driven off by heat, and the other half of the solution is added. At the end of twenty-four hours a heavy oil deposits, which contains an amount of sulphur corresponding to the formula $\text{Sn}_2(\text{C}_4\text{H}_5)_3\text{S}$. When the alcoholic solution of the oxide of sesquistannethyl is saturated with HS, a crystalline mass is formed, which probably contains hydrosulphuret or a higher sulphide. The liquor decanted from this, deposits other crystals having a repulsive odour somewhat resembling that of mercaptan.

Carbonate of Sesquistannethyl.—The alcoholic solution of the hydrated oxide of sesquistannethyl, when evaporated slowly in the air, absorbs carbonic acid and deposits small brilliant crystals of the carbonate. It can be made more easily by the double decomposition of the sulphate of the radical and carbonate of ammonia, and then is obtained in the form of a white powder, which crystallizes from an ethereal solution in oblique prisms.

Phosphate of Sesquistannethyl is formed by the action of phosphoric acid on the carbonate. It is a crystalline powder soluble in dilute alcohol. The arseniate may be prepared in the same way. The iodate and bromate are deposited in small crystals when the iodide or bromide is prepared by the action of iodine or bromine on the oxide of sesquistannethyl. The author has also prepared the formate, acetate, butyrate, and oxalate of sesquistannethyl. Two tartrates are obtained by the action of tartaric acid on the carbonate,—one a bibasic salt which crystallizes in cubes, the other an acid salt which separates in rhombic crystals after the former has deposited. The chloride of sesquistannethyl forms double salts with the chlorides of platinum, gold, and mercury. With the chloride of platinum it forms two compounds: the first is obtained by beautiful crystals of a deep red colour, and has the formula $\text{Sn}_2(\text{C}_4\text{H}_5)_3\text{Cl} \cdot 2\text{PtCl}_2$; the solution which yielded this, afterwards deposits yellow crystals, which have a disagreeable odour, and the composition $\text{Sn}_2(\text{C}_4\text{H}_5)_3\text{Cl} \cdot \text{PtCl}_2$.

Cyanate of Sesquistannethyl is formed by the action of cyanate of silver on the iodide in alcoholic solution. The action of ammonia on an alcoholic solution of the cyanate

forms crystals of a body which the author regards as urea, in which an atom of hydrogen is replaced by sesquistanethyl. The crystals contain $N_2 \cdot H_3 [Sn_2 (C_4 H_5)_3] C_2 O_3$. Kulmiz has also formed acicular crystals of what he supposes to be the iodide of sesquistanethyl-ammonium, $N [Sn_2 (C_4 H_5)_3] H_3 I$, by heating in a sealed tube an alcoholic solution of the iodide saturated with ammonia.

MISCELLANEOUS.

INTERNATIONAL EXHIBITION OF 1862.

AMENDED AND ADDITIONAL DECISIONS OF HER MAJESTY'S COMMISSIONERS ON POINTS RELATING TO THE EXHIBITION.

April, 1861.

1. Her Majesty's Commissioners have fixed upon Thursday, the 1st day of May, 1862, for opening the Exhibition.
2. The Exhibition building will be erected, on a site adjoining the gardens of the Royal Horticultural Society, and in the immediate neighbourhood of the ground occupied in 1851, on the occasion of the first International Exhibition.

3. The portion of the building to be devoted to the exhibition of Pictures will be erected in brick, and will occupy the entire front towards Cromwell Road; the portion in which Machinery will be exhibited will extend along Prince Albert's Road, on the west side of the gardens.

4. All works of industry to be exhibited should have been produced since 1850. The decision whether goods, proposed to be exhibited, are admissible or not, must, in each case, eventually rest with Her Majesty's Commissioners.

5. Subject to the necessary limitation of space, all persons, whether designers, inventors, manufacturers, or producers of articles will be allowed to exhibit; but they must state the character in which they do so.

6. Her Majesty's Commissioners will communicate with Foreign and Colonial exhibitors only through the Commission which the Government of each Foreign Country or Colony may appoint for that purpose; and no article will be admitted from any Foreign Country or Colony without the sanction of such Commission.

7. No rent will be charged to exhibitors.

8. Every article produced or obtained by human industry, whether of

Raw materials,
Machinery,
Manufactures, or
Fine Arts,

will be admitted to the Exhibition, with the exception of,

1. Living animals and plants.

2. Fresh vegetable and animal substances, liable to spoil by keeping.

3. Detonating or dangerous substances.

Copper caps, or other articles of a similar nature, may be exhibited, provided the detonating powder be not inserted; also Lucifer Matches, with imitation tops.

9. Spirits or alcohols, oils, acids, corrosive salts, and substances of a highly inflammable nature, will only be admitted by special written permission, and in well-secured glass vessels.

10. The articles exhibited will be divided into the following classes:—

SECTION I.

Class 1. Mining, Metallurgy, and Mineral Products.

„ 2. Chemical Substances and Products, and Pharmaceutical Processes.

„ 3. Substances used for Food, including Wines.

„ 4. Animal and Vegetable Substances used in Manufactures.

SECTION II.

Class 5. Railway Plant, including Locomotive Engines and Carriages.

„ 6. Carriages not connected with Rail or Tram Roads.

„ 7. Manufacturing Machines and Tools.

„ 8. Machinery in general.

„ 9. Agricultural and Horticultural Machines and Implements.

„ 10. Civil Engineering, Architectural, and Building Contrivances.

„ 11. Military Engineering, Armour and Accoutrements, Ordnance, and Small Arms.

„ 12. Naval Architecture, Ship's Tackle.

„ 13. Philosophical Instruments and Processes depending upon their use.

„ 14. Photographic Apparatus and Photography.

„ 15. Horological Instruments.

„ 16. Musical Instruments.

„ 17. Surgical Instruments and Appliances.

SECTION III.

Class 18. Cotton.

„ 19. Flax and Hemp.

„ 20. Silk and Velvet.

„ 21. Woollen and Worsted, including Mixed Fabrics generally.

„ 22. Carpets.

„ 23. Woven, Spun, Felted, and Laid Fabrics, when shown as specimens of Printing or Dyeing.

„ 24. Tapestry, Lace, and Embroidery.

„ 25. Skins, Fur, Feathers, and Hair.

„ 26. Leather, including Saddlery and Harness.

„ 27. Articles of Clothing.

„ 28. Paper, Stationery, Printing, and Bookbinding.

„ 29. Educational Works and Appliances.

„ 30. Furniture and Upholstery, including Paperhangings, and Papier-maché.

„ 31. Iron and General Hardware.

„ 32. Steel and Cutlery.

„ 33. Works in Precious Metals, and their imitations, and Jewellery.

„ 34. Glass.

„ 35. Pottery.

„ 36. Manufactures not included in previous classes.

SECTION IV.—MODERN FINE ARTS.

Class 37. Architecture.

„ 38. Paintings in Oil and Water Colours, and Drawings.

„ 39. Sculpture, Models, Die-sinking, and Intaglios.

„ 40. Etchings and Engravings.

11. Prizes, or rewards for merit, in the form of medals, will be given in Sections I. II. III.

12. Prices may be affixed to the articles exhibited in Sections I. II. III.

13. Her Majesty's Commissioners will be prepared to receive all articles which may be sent to them, on or after Wednesday the 12th of February, and will continue to receive goods until Monday, the 31st of March, 1862, inclusive.

14. Articles of great size or weight, the placing of which will require considerable labour, must be sent before Saturday, the 1st of March, 1862; and manufacturers wishing to exhibit machinery, or other objects that will require foundations or special constructions, must make a declaration to that effect on their demands for space.

15. Any exhibitor whose goods can be properly placed together, will be at liberty to arrange such goods in his own way, provided his arrangement is compatible with the general scheme of the Exhibition and the convenience of other exhibitors.

16. Where it is desired to exhibit processes of manufacture, a sufficient number of articles, however dissimilar, will be admitted for the purpose of illustrating the pro-

cess; but they must not exceed the number actually required.

26. Exhibitors will be required to deliver their goods at such part of the building as shall be indicated to them, with the freight, carriage, portage, and all charges and dues upon them paid.

27. The vans will be unloaded, and the articles and packages taken to the places appointed in the building, by the officers of Her Majesty's Commissioners.

28. Upon receipt of notice from Her Majesty's Commissioners, that the articles are deposited in the building, exhibitors, or their representatives, or agents, must themselves unpack, put together, and arrange their goods.

29. Packing cases must be removed at the cost of the exhibitors or their agents, as soon as their goods are examined and deposited in charge of the Commissioners. If not removed within three days of notice being given, they will be disposed of, and the proceeds, if any, applied to the funds of the Exhibition.

35. No counters, or fittings, will be provided by Her Majesty's Commissioners. Exhibitors will be permitted, subject only to the necessary general regulations, to erect, according to their own taste, all the counters, stands, glass frames, brackets, awnings, hangings, or similar contrivances which they may consider best calculated for the display of their goods.

36. Exhibitors, or their representatives, should provide whatever light temporary covering may be requisite (such as sheets of oiled calico), to protect their goods from dust; and, in the case of machinery and polished goods, should make the requisite arrangements for keeping the articles free from rust during the time of the Exhibition.

43. Exhibitors must be at the charge of insuring their own goods, should they desire this security. Every precaution will be taken to prevent fire, theft, or other losses, and Her Majesty's Commissioners will give all the aid in their power for the legal prosecution of any persons guilty of robbery or wilful injury in the Exhibition, but they will not be responsible for losses or damages of any kind which may be occasioned by fire or theft, or in any other manner.

44. Exhibitors may employ assistants (male or female) to keep in order the articles they exhibit, or to explain them to visitors, after obtaining written permission from Her Majesty's Commissioners; but such assistants will be forbidden to invite visitors to purchase the goods of their employers.

50. Articles once deposited in the Building will not be permitted to be removed without written permission from Her Majesty's Commissioners.

55. Her Majesty's Commissioners will provide shafting, steam (not exceeding 30 lbs. per inch), and water, at high pressure, for machines in motion.

56. Persons who may wish to exhibit Machines, or trains of Machinery, in motion, will be allowed to have them worked, as far as practicable, under their own superintendence, and by their own men.

70. Intending exhibitors in the United Kingdom are requested to apply, without delay, to the Secretary to Her Majesty's Commissioners, for a *Form of Demand for Space*, stating, at the same time, in which of the four Sections they wish to exhibit.

100. Foreign and Colonial exhibitors should apply to the Commission, or other Central Authority appointed by the Foreign or Colonial Government, as soon as notice has been given of its appointment.

101. Her Majesty's Commissioners will consider that to be the Central Authority in each case which is stated to be so by the Government of its country, and will only communicate with Exhibitors through such Central Body.

102. No articles of foreign manufacture, to whomsoever they may belong, or whosoever they may be, can be admitted for exhibition, *except with the sanction of the Central Authority of the country of which they are the pro-*

duce. Her Majesty's Commissioners will communicate to such Central Authority the amount of space which can be allowed to the productions of the country for which it acts, and will also state the further conditions and limitations which may from time to time be decided on with respect to the admission of articles. All articles forwarded by such Central Authority will be admitted, provided they do not require a greater aggregate amount of space than that assigned to the country from which they come; and, provided also, that they do not violate the general conditions and limitations. It will rest with the Central Authority in each country to decide upon the merits of the several articles presented for exhibition, and to take care that those which are sent are such as fairly represent the industry of their fellow-countrymen.

103. Separate space will be allotted to each foreign country, within which the Commissioners for that country will be at liberty to arrange the productions entrusted to them in such manner as they think best, subject to the condition that all machinery shall be exhibited in the portion of the building specially devoted to that purpose, and all pictures in the fine art galleries, and to the observance of any general rules that may be laid down by Her Majesty's Commissioners for public convenience.

104. By arrangements made with Her Majesty's Government, all Foreign or Colonial goods intended for exhibition, sent and addressed in accordance with regulations hereafter to be issued, will be admitted into the country, and transmitted to the Exhibition building without being previously opened, and without payment of any duty. But all goods which shall not be re-exported at the termination of the Exhibition will be charged with the proper duties, under the ordinary Customs' Regulations.

109. It is not the intention of Her Majesty's Commissioners to take any steps in reference to the protection of inventions or designs, by patent or registration, the law on these points having been materially simplified since 1851.

ANSWERS TO CORRESPONDENTS.

* * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

* * All Editorial Communications are to be addressed to Mr. CROOKER, and Advertisements and Business Communications to the PUBLISHERS, GRIFFIN, BORN & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

VOL. II. of the *CHEMICAL NEWS*, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1861, and will be complete in 26 numbers.

O. A. P.—The article you refer to was given three weeks ago in our pages.

W. H. W.—The diagrams will be given. Chevreul's "Circles Chromatiques" can be obtained at Baillière's, in Regent Street.

F. R. S. A.—Hypochlorous acid is best prepared by passing well-washed and dry chlorine gas over-precipitated and dried red oxide of mercury in a glass tube. The tube must be kept cool, and the gas passed slowly, when chloride of mercury and hypochlorous acid are produced; the latter is to be collected by displacement. Precipitated oxide of mercury must be used, as the crystalline oxide will not answer.

W. P.—We will try and give you the desired information next week.

A Lover of Science.—1. Use benzol instead of camphine. The whole of the gum will not dissolve; the solution must be strained from the residue. 2. Chloride of lead is precipitated as a white powder upon the addition of chloride of sodium to acetate of lead—both in solution. 3. Aldehyde is prepared by carefully distilling 6 parts of oil of vitriol, 4 parts of rectified spirits of wine, and 4 parts of water, with 6 parts of powdered binoxide of manganese. Distil at a gentle heat till 6 parts have come over. Collect in a receiver cooled with ice.

VOL. III. No. 75.—May 11, 1861.

WATER ANALYSIS.

STATEMENT OF THE RESULTS.

No branch of analytical chemistry is, perhaps, better defined or less liable to error than the methods usually employed to detect the presence, and determine the amounts respectively, of the several bases and acids likely to occur in the examination of a sample of spring water; but no sooner is an accurate estimate of the individual constituents arrived at, than difficulties are experienced in drawing up a statement of the results which shall correctly represent the mode of combination and arrangement of the several saline constituents held together in solution by the water. Much diversity of opinion appears yet to exist with regard to the system to be adopted in these cases; some Analysts following the recommendation of Fresenius, whilst others, working according to systems peculiarly their own, have arrived certainly at very anomalous conclusions in reference to the co-existence of salts in solution.

We remember to have heard, many years since, an anecdote bearing so directly on the subject in hand that we may be excused for mentioning it here. It is related of one of our early but distinguished Chemists, who, on reporting the analysis of an ordinary spring water sent to him for examination, had combined the sulphuric acid with the magnesia, sodium with chlorine, lime with carbonic acid, &c., and thus represented the water to contain not only common salt and chalk, but also a large proportion of Epsom salt; whereupon his client became alarmed at the highly medicinal character of the spring, which, in his neighbourhood, had acquired some celebrity as an agreeable drinking water. This led to a reconsideration of the analytical results, and it was found that by substituting *chloride* of magnesium for the objectionable sulphate, and gypsum for chalk, that the amended report became then completely satisfactory to all parties.

A recent example of discrepancy in stating the results of the chemical examination of samples of water from the same locality is presented in the April issue of the *Quarterly Journal of the Chemical Society*. The saline water of Purton, near Swindon, has been analysed independently by Dr. Noad and by Dr. Voelcker, of Cirencester. Their results were communicated to the Chemical Society on the same evening, and the tabulated statements are brought together on contiguous pages of the Society's *Journal* and in the columns of the *CHEMICAL NEWS*.¹ It will be seen that there are many points of general agreement in these analyses, but there is also a notable discrepancy as regards the state of combination of the lime. Dr. Noad advances experiments to prove that nearly half the amount of lime is present in the water as carbonate, since this proportion is precipitated on boiling. Dr. Voelcker maintains, on the contrary, that *potash* is present as carbonate, and the lime *all* as sulphate. This latter supposition may not, perhaps, be

directly contradicted by the known reaction of carbonate of potash upon sulphate of lime, but involves at least the necessity of assuming this to be the more probable state of combination. In regard also to that frequent constituent of saline waters, chloride of magnesium, Dr. Noad's analysis exhibits a fair proportion, but in Dr. Voelcker's Table this item is altogether unrepresented.

What has been stated above in reference to the satisfactory nature of the tests for inorganic constituents in water does not, unfortunately, equally apply to the determination of organic matter. It were much to be desired that better methods could be found for determining with greater accuracy the amount of dissolved organic impurities contained in samples of water. The process usually followed is difficult of execution, and takes no account of the particular *kind* of organic matter which may be present. Whether peaty or nitrogenous in its nature, harmless or injurious, all come under the general category "organic matter." Neither can it be said that the division into *crenic* and *apocrenic* acids has, since the first introduction of these names, served to convey any clearer idea of the nature of these organic bodies.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Chemical Researches on Combustible Minerals,
by M. E. FREMY.

MY long-pursued studies on vegetable tissues, of which the Academy already knows the principal results, have naturally led me to wish to determine the chemical characteristics of the combustible minerals, and to try to discover whether their constituent materials present any analogy with those forming unaltered vegetable tissues.

Admitting, as do all geologists, that turf, lignite, coal, and anthracite, are formed under different circumstances, and that they appertain to the strata of different epochs, my desire is to discover in these combustibles the degree of alteration of the organic tissue.

In studying turf, I have discovered no really new fact. By the side of the unaltered elementary organs, found in such large quantities in fibrous turf, I have found, according to the degree of alteration the combustible has undergone, various proportions of those brown compounds, neutral or acid, nitrogenised or not, which, in our ignorance, we designate by the general term of ulmic compounds. The presence of these bodies, which M. Payen has already investigated, establishes a very clear distinction between turfs and unaltered organic tissues.

The chemical examination of lignites was likely to prove more interesting. In this examination I have taken care to distinguish those specimens still presenting

¹ See *CHEMICAL NEWS*, Vol. III. p. 77.

a ligneous organisation from those which have the appearance and compactness of coal. The former constitute the xyloid lignite, or fossil-wood; the latter, compact and perfect lignite. Regarding their chemical characteristics, all the varieties of lignite I have examined are included in the two preceding species.

Although the fossil-wood lignite has often the tenacity and appearance of ordinary wood, I have come to the conclusion that in this combustible the ligneous tissue undergoes a great change; trituration reduces it to fine powder; submitted to the action of a weak solution of potash, it yields to the alkali a considerable quantity of ulmic acid.

The following two reactions establish a very marked difference between ordinary wood and fossil-wood lignite:—

When nitric acid, by the aid of heat, reacts on wood, it dissolves a portion only of its fibres and medullary rays, and leaves untouched the cellulose matter, which dissolves without colouration in concentrated sulphuric acid, and possesses all the properties ascribed to it by M. Payen.

Under the same circumstances, fossil-wood lignite is attacked with great energy and completely transformed into a yellow resin, soluble in alkalies and in excess of nitric acid.

By submitting wood and fossil-wood lignite comparatively to the action of hypochlorites there is a marked difference in their effects on the two substances.

Hypochlorites re-act on wood in a manner which may be compared to that of nitric acid. They dissolve rapidly a portion of the fibres and medullary rays, leaving the cellulose untouched.

Alkaline hypochlorites attack fossil-wood lignite, almost entirely dissolving it, leaving only imponderable colourless traces of the fibres and medullary rays.

It results, then, from the preceding facts, that when ligneous tissues arrive at that state of modification constituting fossil-wood lignite, and while preserving the appearance of wood, their substance has undergone a very material modification, and then contains new proximate principles, characterised by their perfect solubility in nitric acid and in hypochlorites.

After determining the chemical characteristics of fossil-wood lignite, it becomes interesting to ascertain whether the compact lignite, in which the texture of the ligneous tissues is no longer observable, and which is black and brilliant like coal, to which it bears so much analogy as to mystify the most experienced, preserves the chemical characteristics of fossil-wood lignite or whether it resembles coal.

In a geological point of view, the comparative study of fossil-wood lignite, of compact lignite, and of coal appears to me to be also of great importance. If, in fact, there is a positive connection between the state of alteration of combustible minerals and the age of the strata containing them, it becomes apparent how much geology would benefit by possessing a chemical character, by means of which it would be possible to determine accurately the extent of the modification of an organic body, and of determining the age of the stratum by the state of alteration of the combustible mineral found therein. Therefore, I have applied myself to find a series of chemical re-agents acting differently on combustibles, minerals, and to arrange their varieties conformably to the degree of their modifying action and the chemical characters they would thus present. The re-agents I have employed are potash, hypochlo-

rites, sulphuric and nitric acids. I also take into account the excellent characteristic given by M. Cordier.

I have previously shown that it is impossible to confound ligneous tissue with fossil-wood lignite, the latter being soluble in hypochlorites and nitric acid. Compact lignite presenting no longer the appearance of organisation could be confounded only with certain varieties of coal. The mode of combustion, the reaction of the volatile products on litmus, and the colour of the dust, constitute already distinctive and very important characteristics. To this subject chemical re-agents will give a yet greater degree of certainty. When compact lignite is submitted to the action of concentrated potash, the liquid sometimes becomes coloured brown, dissolving a small quantity of ulmic acid; but alkaline liquid does not generally re-act on the combustible. Thus a distinction is immediately established between fossil-wood and compact lignite.

I have always observed that the lignites which resist the action of potash are those which, by their bearing, approach nearest to the coal series.

Compact lignites, black and brilliant like coal, dissolve entirely in alkaline hypochlorites, are rapidly attacked by nitric acid, and produce the yellow resin which I have already mentioned while treating of fossil-wood lignite.

The two characters just indicated prevent, then, the confounding lignites with coals. Coal, in fact, is not dissolved by hypochlorites, and is attacked but feebly by nitric acid. I have submitted to the test of the hypochlorites almost all the important coals belonging to different strata, and have found that these combustibles always resist the action of these chemical re-agents. To me this characteristic appears so valuable that I think were a sample of coal met with slightly attackable by hypochlorites, it would be advisable to examine whether the combustible possessing this exceptional property were really coal; for it may well be imagined that in coal-fields there may exist vegetable matters unequally decomposed.

Coal and anthracite which resist the action of alkaline and hypochlorite solutions dissolve completely in a mixture of monohydrated sulphuric acid and nitric acid; the liquid takes a very deep brown colour, and holds in solution an ulmic compound, which water completely precipitates.

It is not my intention in this paper to consider the influences by which organic tissues are transformed into combustible minerals. I ought, however, here to put on record what seems to me an interesting observation. I have ascertained that ligneous tissue, exposed for several days to a temperature of 200°, undergoes successive modifications, and yields bodies very similar to those found in lignites. The first are soluble in alkalies, and correspond to fossil-wood lignite; the second are insoluble in alkalies, but dissolve entirely in hypochlorites, like compact lignite. These are the new facts which it is my wish to submit to the Academy. Their evident object is to introduce chemical characteristics into the study of combustible minerals, and they appear to me to lead to the following deductions:—

1. By treating combustible minerals by the above-mentioned re-agents, it is ascertained that in proportion to the age of the lignite so the chemical characteristics of the tissues gradually disappear, and the organic matter more resembles graphite the older the stratum whence it is derived. One exception I make in respect of the strata which have been modified under the influence of metamorphism. My researches accord completely with

those of M. Regnault, who has already arrived at the same conclusions as myself in his important researches on combustible minerals.

2. The first degree of modification of ligneous tissues represented by turf is characterised by the presence of ulmic acid, and also by the ligneous tissues or cellules of the medullary rays, which can be extracted and purified in considerable quantities by means of nitric acid or of hypochlorites.

3. The second degree of modification corresponds to fossil-wood, or xyloid lignite. It is partly soluble in alkali, like the preceding body; but it undergoes a greater alteration, for it dissolves almost entirely in nitric acid and hypochlorites.

4. The third state of modification is represented by compact or perfect lignite. Re-agents indicate in this substance a transition from organic matter to coal: thus, alkaline solutions have generally no effect on perfect lignite; this combustible is characterised by its complete solubility in hypochlorites and nitric acid.

5. The fourth degree of modification corresponds to coal, which is insoluble in alkaline solutions and in hypochlorites.

6. The fifth degree of alteration is anthracite, which is obviously allied to graphite, which resists the re-agents capable of modifying the preceding combustibles, and which is but very feebly attacked by nitric acid.

It is, then, evident that chemical reactions confirm the classification of the combustible minerals admitted by geologists. I am, however, far from thinking that lignite, coal, and anthracite, which are now characterised by their elementary composition and chemical reactions, constitute the only modifications which organic matters undergo while changing into combustible minerals. There doubtless are intermediate transformations of the organic tissues corresponding to the differences established by commercial practice between the different species of coal and lignites. But are the re-agents sufficiently sensitive to be capable of characterising these different varieties of the same combustible mineral in glance-coal or smith-coal, or even in the different layers of the same coal-bed? I shall investigate this question in another communication.—*Comptes-Rendus.*

On Some Applications of the Ferrocyanide of Potassium in Chemical Analysis, by EDMUND W. DAVY, A.B., M.B., M.R.I.A., Professor of Agriculture and Agricultural Chemistry to the Royal Dublin Society.¹

(Continued from page 276.)

Having made two standard solutions, the first containing 21.122 grammes of ferrocyanide of potassium in a litre of the solution, and the second 14.759 grammes of bichromate of potash in the same quantity of solution (weights which are to each other as their atomic equivalents), I made several estimations of chloride of lime with them, adopting the method I have just described, and found that it gave the most consistent results, and which agreed very closely with those obtained by Gay-Lussac's and Otto's methods when the latter were performed with the greatest care, the only difference being that the results obtained by my method indicated a few hundredths of a part more of chlorine than either of those methods did, which may be accounted for by the unavoidable loss of a minute quantity of chlorine which takes place in those processes.

¹ From the *Philosophical Magazine*, being part of a paper read before the Royal Dublin Society, December 17, 1860.

In order to simplify the process and render the calculation as short as possible, I would recommend for commercial valuations the following way of carrying out this principle:—Having obtained a flat-bottomed flask or bottle, which will contain 10,000 grains of distilled water when filled up to a certain mark in the neck, make two standard solutions, the first by placing in the flask or bottle 1190 (or exactly 1189.97²) grains of the purest crystallised ferrocyanide of potassium (yellow prussiate of potash), reduced to powder, adding distilled water to dissolve the salt, and when this is effected, filling up with water to the mark; and having mixed the solution thoroughly, place it in a well-stoppered bottle. The second standard solution is made in the same manner, substituting for the ferrocyanide 138.6 (or exactly 138.58) grains of bichromate of potash which has been purified by re-crystallisation and fused in a crucible at as low a heat as possible. Both these solutions will keep unchanged, and will answer for a number of determinations if they are preserved in well-stoppered bottles, and the ferrocyanide solution be kept, when not in use, excluded from the light. Get a burette or alkalimeter capable of holding or delivering 1000 grains of distilled water, and divided into 100 equal divisions; also two small bottles, one capable of delivering 1000 grains, and the other 500 grains of distilled water when filled up to a certain mark on the neck of each,³ which may both be readily made by filling them with water, emptying them, and, after they have drained for a minute or two, weighing into each the above weights of distilled water; or, what will be sufficiently accurate for most purposes, pour from the burette into one 100 divisions of distilled water, and into the other 50, and mark with a file where the fluid stands in the neck of each bottle. Having these all ready, take an average specimen of chloride of lime, and weigh out 100 grains of it, and make in the usual way a solution of it by trituration in a mortar with some water; pour it into the flask which was used in preparing the two standard solutions, and, having filled up with water to the mark in the neck, mix the solution thoroughly; and before each time that any of the chloride of lime is taken out, shake well the contents of the flask.

Measure out into a beaker-glass, by means of the two little bottles, 100 divisions of the chloride of lime solution, and 50 of the standard solution of ferrocyanide; and, having mixed them well together, add some hydrochloric acid to dissolve the precipitate formed and acidify the mixture strongly; and having mixed the whole well, pour from the burette slowly the standard solution of bichromate, stirring well all the while, till a drop taken from the mixture and brought in contact with a drop of a very weak solution of perchloride of iron produces a yellowish-brown colour, as already noticed. Then read off the number of divisions of the standard solution of bichromate which was necessary to produce this effect, and this being deducted from 50, gives the per-centage by weight of chlorine.

For the standard solution of ferrocyanide having been made so that the 10,000-grain measures should be equivalent to 100 grains of chlorine, and as every division of

² The above numbers are obtained as follows:—35.5 parts of chlorine are capable, as before stated, of converting 422.44 parts of the crystallised ferrocyanide of potassium into ferridcyanide; therefore, 100 parts of the former will convert 1189.97 parts of the latter into the same compound. Again, as before observed, 1267.32 parts of the crystallised ferrocyanide require 147.59 parts of the bichromate of potash to convert them into the ferridcyanide; 1189.97 parts, therefore, will take 138.58 parts of that salt to produce the same effect.

³ Two small pipettes capable of delivering the above quantities would be found still more convenient.

the burette equals 10 grains, each of these divisions of the ferrocyanide solution converted into ferridcyanide will indicate 0.1 grain of chlorine. Again, the 100 divisions of the solution of chloride of lime represent 10 grains of that substance, and we want to know how many divisions of the ferrocyanide solution its chlorine has converted into ferridcyanide. This is readily ascertained by the bichromate solution, which has been so graduated that each division represents a division of the ferrocyanide solution. So that to determine the percentage of chlorine, we have only to deduct, as before stated, the number of divisions of the bichromate solution employed from the 50 of the ferrocyanide solution, and the difference gives us the percentage of chlorine by weight in the sample; thus, in four experiments 50 divisions of the ferrocyanide solution, mixed with 100 divisions of the solution of chloride of lime, required 18.5 divisions of the bichromate solution to convert the whole of the ferrocyanide employed into ferridcyanide; this number, taken from 50, leaves 31.5 divisions of ferrocyanide, which were converted into ferridcyanide by the chlorine of the chloride of lime; and as each division represents 0.1 grain of chlorine, 31.5 will be equivalent to 3.15 grains of chlorine, which is the amount contained in 10 grains of the sample; consequently, 100 grains will contain 31.5 grains of chlorine, which is the same amount as is obtained by simply deducting the number of divisions of bichromate solution employed from 50 of ferrocyanide used in the estimation.

Though this process appears a long one, from the details which are necessary to explain its principle, yet in practice it is very expeditious, and requires only a very few minutes for its performance, and is much quicker than either Gay-Lussac's or Otto's method.

Though I have as yet chiefly confined my attention to the use of the ferrocyanide of potassium in the estimation of chlorine in bleaching powder, I have no doubt that it may be advantageously employed in many other useful determinations by carrying out the principles already explained: thus, for example, it may be used as a means of determining the amount of bichromate of potash present in a sample of that salt, or the quantity of chromic acid that exists under different circumstances. Again, the same salt may be used in different determinations where a certain amount of chlorine is liberated, which represents a proportional quantity of some other substance: thus, for example, in the estimation of manganese ores for commercial purposes, where they are heated with hydrochloric acid, the quantity of chlorine disengaged will indicate a certain amount of peroxide of manganese in the ore, on the presence of which its commercial value almost entirely depends; and the chlorine evolved may be estimated by absorbing the gas in a dilute solution of caustic potash, and then determining the amount of chlorine in it by precisely the same process as that I have recommended in the valuation of chloride of lime. To test the accuracy of this method, I heated in a small flask a given quantity of pure bichromate of potash with an excess of strong hydrochloric acid, and collected the evolved chlorine by means of a dilute solution of caustic potash, employing the bulb retort and curved dropping-tube, as recommended by Bunsen in the "*Analysis of the Chromates*" (see the last edition of Fresenius's "*Quantitative Analysis*," page 234), and ascertained afterwards, by the use of the ferrocyanide of potassium, the amount of chlorine evolved, which corresponded almost exactly with the calculated amount of that substance which should have been obtained by the action of the quantity

of bichromate used on the hydrochloric acid. Again, a standard solution of ferrocyanide of potassium may be used, as E. de Haen has shown, to determine the strength of the permanganate of potash in the analysis of the ferrocyanide and ferridcyanide of potassium, as an acidified solution of the ferrocyanide, as before stated, rapidly decolorises a solution of permanganate of potash, whereas the ferridcyanide has no action on that salt; and this reaction might be taken advantage of, in the valuation of chloride of lime, to determine the excess of ferrocyanide used in my process, but from my experiments I found that more precise and accurate results were obtained by the use of the bichromate of potash.

The reaction of the bichromate of potash on the ferrocyanide might be employed in the valuation of the ferrocyanide of potassium and other ferrocyanides, having previously, in the case of those which were insoluble, converted them into the ferrocyanide of potassium by boiling them with caustic potash, and separating the insoluble oxides by filtration.

It might also be employed for the valuation of the commercial red prussiate of potash, which is now to some extent employed as a bleaching agent in calico printing, and which consists of varying quantities of ferro- and ferridcyanide of potassium together with chloride of potassium. By ascertaining first how much a given quantity of the sample requires of a standard solution of bichromate of potash to convert the ferrocyanide present into ferridcyanide, the percentage of that substance would be known; and then by taking another portion of the sample and converting the ferridcyanide it contained, by reducing agents, such as the sulphites of soda and potash, &c., into the ferrocyanide, and finally determining the amount of bichromate necessary to bring the whole of the ferrocyanide then present into the state of ferridcyanide, the difference in the two results would indicate the proportion of ferridcyanide originally present in the sample.

The last application of ferrocyanide of potassium which I shall notice in the present communication is its employment as a reducing agent. It has long been known that the cyanide of potassium possesses most powerful reducing properties, and has been very usefully employed for that purpose in the reduction of different metallic salts under various circumstances; but I am not aware that the ferrocyanide of potassium has been proposed or used for similar purposes; at least, I have referred to a great number of analytical and general chemical works, and in none of them is this salt recommended as a reducing agent, though the cyanide is so much extolled for that purpose. According to my experiments, the ferrocyanide is a far more convenient reducing agent than the cyanide, and may be substituted for it in many cases of reduction with the best results, as it possesses many unquestionable advantages over that salt for this purpose. Thus, the ferrocyanide does not deliquesce and decompose when exposed to the air, whereas the cyanide rapidly absorbs moisture, and, unless kept in very well-stoppered bottles, becomes quite wet, and in this state quickly decomposes; and this deliquescence on the part of the cyanide is often a source of much inconvenience in its use as a reducing agent, owing to the almost unavoidable absorption of more or less moisture which takes place in mixing it with the substance to be reduced, and during the introduction of the mixture into the reducing-tube. The ferrocyanide, on the other hand, in a thoroughly dried and finely-powdered state, can be intimately mixed with the substance without any appreciable absorption of moisture.

I made the following comparative experiment to ascertain the relative absorptive properties for moisture of the two salts under the same circumstances:—Having thoroughly dried in a water-oven, till it ceased to vary in weight, some finely-powdered ferrocyanide, I placed 50 grains of it in a counterpoised watch-glass, and powdering in a warm mortar some fresh cyanide of potassium, I placed the same quantity of it in a similar counterpoised watch-glass, and left them both exposed to the air. On examining them after four hours' exposure, I found that the former had only gained $\frac{1}{10}$ th parts of a grain of moisture, whereas the latter had taken up 3.6 grains, or sixty times as much moisture under the same circumstances. After two days' exposure I found that nearly all the cyanide had passed into the liquid condition, having taken up 4.6 grains of water; whereas the ferrocyanide appeared perfectly dry, and had only absorbed 1.4 grain.

The great fusibility of the cyanide is sometimes rather a disadvantage, which has to be lessened by mixing it with a certain proportion of dried carbonate of soda; but the ferrocyanide not fusing at so low a temperature, does not require in most cases this admixture to lessen its fusibility. Again, the ferrocyanide is not a poisonous salt, whereas the cyanide is highly so, and must be used with great caution; and, lastly, the former salt is little more than half the price of the latter. Combined with the above advantages, I find that the ferrocyanide is equally effective in reducing metallic oxides and sulphurets, and is especially convenient for the reduction of different combinations of arsenic and mercury, which are reduced by it with the greatest ease.

I made several comparative experiments with the dried ferrocyanide and with the cyanide as reducing agents for the sulphuret of arsenic and arsenious acid, employing the same quantity of arsenical compound with each salt, under similar circumstances; and in almost every case, particularly where the quantities operated on were minute, I obtained more satisfactory results with the dried ferrocyanide than with the cyanide.

The following were amongst my experiments:—I mixed the $\frac{1}{10}$ th of a grain of sulphuret of arsenic with 3 grains of the dried ferrocyanide, and made a similar experiment, substituting the same quantity of cyanide; and, on heating the mixtures in similar glass tubes, obtained almost identically fine and characteristic rings of metallic arsenic.

I then intimately mixed the same quantity of sulphuret of arsenic with 49.9 grains of very finely-powdered glass, and taking 5 grains of this mixture, containing the $\frac{1}{10}$ th part of a grain of the sulphuret, mixed it with 5 grains of the dried ferrocyanide, and made a comparative experiment with another 5 grains of the mixture, substituting the same quantity of cyanide: on heating both these mixtures in small reduction-tubes, I got the characteristic metallic rings in both, but better defined in the case of the ferrocyanide.

I finally took 2.5 grains of the mixture of sulphuret and glass, containing about $\frac{1}{1000}$ th parts of a grain of sulphuret of arsenic, and treated them in the same manner, using in one case 2.5 grains of ferrocyanide, and in the other 2.5 grains of cyanide, and obtained in each case a minute metallic ring, which, however, was much more distinct and satisfactory where the ferrocyanide had been used as the reducing agent.

The same comparative experiments were made with arsenious acid, when results similar to those in the case of the sulphuret of arsenic were obtained.

The ferrocyanide, therefore, is a most delicate reducing

agent in the case of arsenical compounds, and where very minute quantities have to be detected, appears from my experiments to give more satisfactory results than the cyanide.

Whether the addition of dried carbonate of soda would improve the ferrocyanide for some cases of reduction, I am not at present able to say; but in one experiment which I made with the sulphuret of arsenic, I obtained as good results, using the ferrocyanide alone, as where it was mixed previously with its own weight of dried carbonate of soda. In many cases the ferrocyanide may be used as a reducing agent in a state of powder without separating its water of crystallisation; but, in most cases, it will be rendered a far better reducing agent by being previously dried at 212° in a water-bath or oven; and in this dried condition it may be kept for any length of time in a good-stoppered or well-corked bottle.

Though as yet my experiments have been chiefly confined to the reduction of different compounds of arsenic and mercury, I entertain no doubt that the ferrocyanide of potassium will be found an equally effective reducing agent in the case of the combinations of other metals, and that it may with great advantage be substituted for the cyanide of potassium in many cases where the latter salt is used as a reducing agent.

On Aniline Red, by M. E. KOPP.

I FIND that aniline red, produced by the action of nitric acid or of nitrates of an easily-reducible base, is a triamine, representing mononitro-trianiline,—

The existence of binitro-trianiline seems to me almost certain, as, by treating aniline with a mixture of sulphuric and nitric acid, we obtain a yellowish-brown body, possessing in the highest degree the properties of a nitro compound; but I have not yet succeeded in purifying it sufficiently to make the analysis coincide exactly with the formula.

In trianilines a portion of the hydrogen may be substituted by methyl, ethyl, and amyl, along with nitrous gas. These are very probably the compounds:—

I specified in my paper these substances only as hypothesis, but they really exist. I have already obtained several of them, and it is very remarkable that the red tint disappears, becoming from violet more and more blue, according as the hydrogen is replaced by the hydrocarbons.

The latter are not yet sufficiently pure for analysis, though very beautiful as shades of colour. They are generally almost insoluble in water, but easily soluble in alcohol or acetic acid. When the trianiline, instead of being nitrated, is chlorated, bromated, or iodised, the compound is equally a red matter, but presenting slight differences of tint.

I venture to hope that my work will serve to throw some light on the mode of formation, the composition, and the constitution of the colouring matters, so remarkable and so important, which are derived from aniline.—*Comptes-Rendus.*

On the Properties of Liquid Carbonic Acid,
by GEORGE GORE, Esq.

In this communication the author shows how a small quantity of liquid carbonic acid may be readily and safely prepared in glass tubes closed by stoppers of gutta percha, and be brought in a pure state into contact with any solid substance upon which it may be desired to ascertain its chemical or solvent action, or be submitted to the action of electricity by means of wires introduced through the stoppers.

By immersing about fifty substances in the liquid acid for various periods of time, he has found that it is comparatively a chemically inert substance, and not deoxidised by any ordinary deoxidising agent except the alkali metals. Its solvent power is extremely limited. It dissolves camphor freely, iodine sparingly, and a few other bodies in small quantities. It does not dissolve oxygen salts, and it does not redden solid extract of litmus. It penetrates gutta percha, dissolves out the dark brown colouring matter, and leaves the gutta percha undissolved, and much more white. It also acts in a singular and somewhat similar manner upon india rubber. The india rubber while in the liquid acid exhibits no change, but immediately on being taken out it swells to at least six or eight times its original dimensions, and then slowly contracts to its original volume, evidently from expansion and liberation of absorbed carbonic acid, and it is found to be perfectly white throughout its substance. These effects upon gutta percha and india rubber may prove useful for practical purposes.

The liquid acid is a strong insulator of electricity; sparks (from a Ruhmkorff's coil) which would pass readily through $\frac{1}{2}$ inch of cold air, would with difficulty pass through about $\frac{1}{16}$ th of an inch of the liquid acid.

In its general properties it is somewhat analogous to bisulphide of carbon, but it possesses much less solvent power over fatty substances.—*Proceedings of the Royal Society.*

TECHNICAL CHEMISTRY.

Cyanogen Steel.

It is curious to observe how frequently several inventors are engaged at the same time upon similar discoveries, although each of them may be pursuing his labours altogether independently of the others, and although the discovery may be unquestionably new. At the time when the pneumatic process of refining iron was creating so much attention, it will be remembered that both Mr. Martien and Mr. Bessemer had lodged provisional specifications within three months of each other, consequently the provisional protection accorded to each was running simultaneously, and before the public or any other person but themselves had had an opportunity of ascertaining the details of the respective inventions. About the same time the presence of nitrogen in steel was positively declared by Mr. Christopher Binks, and his project for employing cyanogen compounds in the manufacture of that metal was brought prominently forward. The question, however, of improving the mode of manufacturing steel had at that period been discussed to repletion, and Mr. Binks' assertion was regarded with suspicion, or, at least, as the project of an enthusiastic patent seller. After long remaining in abeyance (the

fact of the discovery being only kept from sinking into oblivion by the occasional lodging of a specification, in which the use of substances capable of yielding cyanogen was incidentally mentioned), the subject has been revived, and is now restored to more than its pristine vigour, by the publication of M. Fremy's communication to the French Academy of Sciences; and it seems probable that cyanogen compounds will ere long be acknowledged to be as necessary to the manufacture of steel as carbon has hitherto been.

In Mr. Fleury's process of manufacturing steel with electricity cyanogen is regarded as a necessary constituent of steel; and several other processes, which have in practice proved to give excellent results, may owe their success to the unintentional introduction of cyanogen compounds. Amongst the specifications of patents issued during the past week, is one relating to an invention by Messrs. Duhesme, De Ruolz, and De Fontenay, for improvements in the manufacture of cast-steel, and in the re-manufacture of old steel, in which the use of cyanogen is again the principal ingredient employed. In making cast-steel according to this invention, certain mixtures of wrought-iron, cast-iron, oxide of iron, old steel, and ferrocyanide of potassium, or ferricyanide of potassium, or some of them are to be employed. The ferrocyanide of potassium is commonly known as yellow prussiate of potash, while the ferricyanide of potassium is commonly known as red prussiate of potash. The corresponding sodium salts may be substituted for the potassium salts. Were the sodium salts used, the process would be almost identical with that of Mr. Charles Sanderson, of Sheffield, also made public several years since. The papers read before the Society of Arts by Mr. Binks, advocating cyanogen, and by Mr. Sanderson, for employing substances capable of yielding cyanogen, for improving the quality of iron and the allied metals, having been presented within a short time of each other. But whether the salts of sodium or those of potassium be used, it is evident that Messrs. Duhesme, De Ruolz, and De Fontenay have been long anticipated, the cyanogen being incontestably the ingredient upon which they rely for success. In the manufacture of cast-steel, they continue, one mixture employed consists of—Wrought-iron, 700 parts by weight; white cast-iron, 200 parts; oxide of iron, 100 parts; red prussiate of potash, 8 parts. A second mixture consists of—Old steel (old files, tools, or springs), 500 parts by weight; wrought-iron, 500 parts; red prussiate of potash, 14 parts. A third mixture consists of—Old steel, 350 parts by weight; wrought-iron, 350 parts; white cast-iron, 200 parts; oxide of iron, 100 parts; red prussiate of potash, 7 parts. A fourth mixture consists of—Wrought-iron, 1000 parts by weight; oxide of iron, 75 parts; red prussiate of potash, 28 parts. From the small proportion of cyanogen added in the several instances, the astonishment that its existence did not long previously attract attention will at once disappear, the quantity of ferricyanide being only such as would cause a very small proportion of cyanogen to remain in the iron at the completion of the process.

If the ferrocyanide be employed instead of the ferricyanide of potash in the mixtures described, double the quantity indicated for the red prussiate of potash is used; but the latter is preferred as giving a more decided reaction, and also on account of its containing no water of crystallisation. Refined iron, or fine metal, may be advantageously substituted for the cast-iron in the first and third mixtures, in which case the quantity

of fine metal employed must be double that indicated for the cast iron, without altering the proportions of red prussiate of potash. The cast-iron employed should be white, and of at least two qualities, one of which should contain manganese. It is to be first broken up into small fragments. The wrought-iron should be in the smallest possible fragments, and it should be avoided to use granular with fibrous iron. Granular iron of a good quality is preferred. The old steel should be of a good quality, and introduced into the mixture in small pieces. For the re-manufacture of old steel one mixture employed consists of old steel, such as old files, tools, or springs, 1000 parts by weight; red prussiate of potash, 10 parts. Another mixture consists of old steel, 1000 parts by weight; yellow prussiate of potash, 20 parts. In carrying out the manufacture of cast-steel, as also the re-manufacture of old steel, according to this invention, the above mixtures have to be melted down in crucibles, the ingredients having been previously mixed as completely as possible. The old steel, as also the wrought and cast-iron, should first be broken into small pieces, and the prussiate of potash should be well distributed throughout the mass. The operations take place in a common air furnace, for which a very pure coke is employed, mixed with a tenth part of wood charcoal. The crucibles must be kept hermetically closed until complete fusion of the metals ensue, and the fire must be managed with the usual precautions. The same description of crucible is employed as is generally used for the smelting of steel. Those of plumbago are preferred; but, if these are used, it is well to increase slightly the proportion of prussiate of potash after the crucibles have been employed for two successive melt-ings.—*Mining Journal*.

A Course of Ten Lectures on Inorganic Chemistry, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

LECTURE VII.

Nitrogen — Preparation and Properties — Compounds of Nitrogen with Oxygen and with Hydrogen. — Carbon — its Properties in the Form of Diamond, Graphite, and Charcoal.

We have to-day to consider an element which, in many respects, presents striking contrasts to the two elements we have hitherto studied. This element is nitrogen, a body which is rather distinguished for the sluggishness of its affinities than for the facility with which it unites with other bodies. On this account, nitrogen exists in nature chiefly in the free or elementary condition. It is contained in this state in the atmosphere, and constitutes about four-fifths of the total volume of atmospheric air, and more than three-fourths of the weight of the atmosphere. It exists, however, also in combination, although in comparison with the quantity contained in the atmosphere this amount in combination should be regarded almost as a vanishing quantity. It exists, however, in the tissues of plants and animals, and is in fact essential to the existence of animal and vegetable life. It is found also in the remains of plant life of former ages; consequently it is a constituent of our coal formations, and exists there to the extent of from one to one and a-half, and even, in some cases, up to two per cent. It is also a constituent of nearly all those highly poisonous vegetable

substances, such as strychnine, brucine, narcotine, and bodies of that kind. It is also an essential element in hydrocyanic acid, that very poisonous prussic acid, as it is sometimes termed, with the properties of which we are all acquainted. There is scarcely any vegetable poisonous substance which does not contain nitrogen. That singular vegetable extract with which the Indians poison their arrows, is, so far as we know at the present time, entirely free from nitrogen. That and the poison of *cocculus Indicus* are nearly the sole exceptions to this general rule that these poisonous vegetable substances invariably contain nitrogen.

We can prepare this element either by abstracting it from the atmosphere, or, in other words, by removing the element with which it is associated in the air, namely, oxygen; or we can extract it from some of its compounds. The first is the most simple mode of proceeding. As nitrogen is remarkable for its want of affinity, and as oxygen is distinguished for its powerful affinities, there are many means by which we can withdraw the oxygen from the nitrogen in the atmosphere, thus leaving the nitrogen in a free state. A common candle will do this, to a certain extent, by burning it in a closed vessel filled with atmospheric air. Under such circumstances, after a certain time, the candle goes out. Now, it goes out when it no longer finds a sufficient quantity of oxygen to continue its combustion; but, unfortunately, a candle will not continue to burn until all the oxygen has been removed. Besides this, it also produces, at first, carbonic acid, and when the candle is about to be extinguished for want of more oxygen it produces carbonic oxide. From the carbonic oxide it is very difficult afterwards to free the nitrogen; and consequently this process of burning a candle in the air would not answer our purpose for procuring free nitrogen. Phosphorus, however, is a substance which is more combustible than a candle is, and which does not generate, on its combination with oxygen, any volatile matter—any gaseous substance—which we should have difficulty in subsequently removing from the nitrogen. Further, the phosphorus is capable of continuing to burn until every trace of oxygen has been removed from the air, and phosphorus, consequently, is well adapted for the preparation of nitrogen, leaving it in a state of comparative purity.

Here is the apparatus by which we effect this. We place a little piece of phosphorus on a small capsule floating on water, and then ignite it by means of a heated wire, and invert over it a bell-jar filled with air. At first we have an expansion of the air contained in the jar, owing to the heat generated by the combustion of the phosphorus, but this expansion will soon cease, and give place to a contraction as the combustion goes on; and we shall notice, I think, when the phosphorus has become extinguished that the gas remaining in the receiver will be considerably less than the bulk of air which the vessel contained at first. Those of you who can see over the edge of this vessel will perceive that even at the present moment the water is gradually rising in the interior. This rising of the water will increase as the temperature of the enclosed nitrogen diminishes. You see the phosphorus burns more and more dimly, and it will finally be extinguished. At the moment of its extinction, the last particle of oxygen will have been removed from the atmospheric air. Now, as we shall subsequently find, atmospheric air consists of particles of oxygen and nitrogen, the nitrogen only remaining after the extinction of the phosphorus. The gas which remains may be regarded as pure nitrogen, or, at all events, nitrogen very nearly pure.

That is one mode of preparing the element. Another plan consists in causing two compounds of nitrogen to decompose each other. If we mix together a compound of nitrogen and hydrogen, which we term ammonia, and a compound of nitrogen and oxygen, which we call hypnitrous acid, we have a solution containing just a sufficient amount of oxygen in the one compound to combine with the hydrogen in the other compound so as to produce

water, leaving the two quantities of nitrogen that were contained in those two compounds in the elementary form. Now, nitrogen, prepared by either of these processes, possesses the following properties: It is a perfectly colourless and transparent gas. Here we have a jar of it, and just as we saw in the case of the oxygen and hydrogen, so here with nitrogen; you cannot distinguish a vessel filled with this gas from another vessel filled with atmospheric air. Here [in the bell-jar in which the phosphorus had just been burnt], at present, we have a quantity of white fumes mixed with our nitrogen. These white fumes consist of phosphoric acid produced by the combustion of phosphorus at the expense of the atmospheric oxygen. This phosphoric acid will gradually subside and dissolve, leaving the gas, after a few minutes, as clear and transparent as that which we have in the other jar, and which was prepared, in fact, by this process. Nitrogen possesses nearly the same specific gravity as atmospheric air. Taking atmospheric air as unity it is slightly more than '97. It is very slightly soluble in water—far less so than oxygen. One hundred volumes of water dissolve only about one and a-half volumes of nitrogen, whilst about double this quantity of oxygen is dissolved. This greater solubility of oxygen than atmospheric nitrogen in water is a most important point connected with the existence of animal life beneath the surface of water. Fishes live in water by means of the atmospheric oxygen which is dissolved in that liquid. They have no power whatever of decomposing the water, and separating the oxygen from the hydrogen; but they require for their respiration free oxygen, just in the same way as animals living in the air; and they receive this oxygen from the quantity of air dissolved in water. If you deprive water of air by placing it under the exhausted receiver of an air-pump for a few moments, fishes placed in that water will very soon die, because they cannot obtain the supply of oxygen which is necessary to continue their respiratory functions. In consequence of water dissolving more oxygen than nitrogen, these animals have, so to speak, a dissolved atmosphere, far richer in oxygen than our ordinary air; and, therefore, by a comparatively much smaller bulk of air than land animals require they can continue their respiration, and obtain quite a sufficient amount of oxygen for their wants.

—In ordinary language we generally describe nitrogen as being incombustible in itself, and incapable of supporting combustion. If we take a jar of it—let us take this jar here, for instance—and plunge into it a lighted taper, we shall see, on the one hand, that when the paper comes in contact with the gas the latter will not inflame, and, on the other hand, that the paper is extinguished when it is lowered into the jar; so that we gather from this experiment that nitrogen is incombustible; but these matters are not to be decided upon the dictum of a single experiment of this kind. It is quite possible that nitrogen may be very combustible at higher temperatures, and indeed we shall find that it is combustible to a certain extent at all events. Different combustibles require very different degrees of heat to set them a burning—to “ignite” them, as we call it. I have here a substance which is so easily ignited that the moment it comes in contact with the air, even at ordinary temperatures, it bursts into flame. I will expel some of it out of this tube—it is a liquid body—into the dish there; and you see this substance, as soon as it comes in contact with the air, ignites and burns brilliantly. Now phosphorus is another combustible body which will furnish us with a second link in this chain. The body which we have just expelled from the tube has its igniting point below the temperature of the atmosphere. The igniting point of phosphorus is higher than the ordinary temperature of the atmosphere, and if we bring a piece of this phosphorus into the air, you see it does not take fire; but it will take fire at a temperature not very much higher than that of the

atmosphere, and if we float it in a copper capsule upon hot water, bring it in contact with the heated surface, our phosphorus will probably then ignite. [A piece of phosphorus was ignited in the manner described.] There you see at that temperature our phosphorus ignites and enters into combustion. Then, again, we have a substance, the bisulphide of carbon, which has an igniting point a little higher than phosphorus, but still far below an ordinary flame. We will warm this glass rod. I need not have it so hot that I cannot bear to draw it through my fingers. With this warm rod I dare say I shall be able to ignite this bisulphide of carbon. Yes; you see it ignites at this temperature, far below any of our usual igniting points. The rod is sufficiently hot, but I can draw it in this way through my fingers, although it possesses power to ignite this inflammable substance. Now, proceeding upwards, the ordinary gas flame which we burn has an igniting point still higher than this bisulphide of carbon, but lower, again, than some other bodies. The ordinary coal gas, if exposed to very bright red heat, ignites; but if it be exposed to a temperature below this very bright redness, that is, if you take an iron bar heated only to dull redness, it will fail to ignite this coal gas. Now, we have here another material which is still less combustible than coal gas; this material is a compound of nitrogen which I shall presently have to explain to you. It is called ammonia, or ammoniacal gas. We are generating it here in this vessel, and passing it through this iron tube which is heated to redness by a gas furnace. I dare say by the aid of that external heat applied to the ammonia we shall get it to burn at the extremity of the tube; but the ammoniacal gas, as we shall presently see, is not ordinarily combustible, but only when previously heated in this way can it continue its combustion. If we allow a jet of ammoniacal gas to impinge on a candle-flame it will burn around the flame, but will not continue its combustion when the flame has been removed; so that if we were to pass this ammoniacal gas simply through a cold tube and endeavour to ignite it at the end we should get no flame from it. Probably, our tube will now be heated sufficiently high. [A light was applied to the end of the tube from which the gas was issuing.] Yes, there our ammoniacal gas burns at the extremity of the tube quite readily. Now we will turn off the gas of the apparatus by which the tube is heated, and you will see that soon after that gas has been extinguished the flame of the ammoniacal gas will gradually withdraw itself from the end of the tube and finally be extinguished. It can no longer retain its ignition, because the temperature produced by the combustion of ammonia is by no means so high as its igniting point. We can only keep the temperature at the igniting point by previously passing the gas through this hot tube. It thus produces a higher temperature, just as you get a higher temperature in a furnace fed by heated air than you do in a furnace fed by ordinary air; and the difference between these five or six hundred degrees of heat is sufficient to raise the temperature of the burning ammoniacal gas beyond its igniting point, and therefore to render it capable of burning in the air. The element nitrogen, to which all these experiments lead us up, has an igniting point still higher than that of any of these substances. It is higher even than that of ammoniacal gas; and we require to expose it to a still higher temperature in order to bring about its combustion with oxygen. Further, like ammoniacal gas, nitrogen on its combustion with oxygen, that is, when you get it to burn by heating it to the proper temperature to render it combustible, produces, in burning, a less amount of heat—I mean to say a lower temperature is produced—than is equal to its igniting point. Its igniting point is higher than the temperature produced on its combustion. On this account the combustion cannot be propagated from particle to particle, or from mass to mass of the mixture of oxygen and nitrogen gases. If this were not the case

it is obvious that all the nitrogen in the air would long ago have been burnt up. The first time that a philosopher obtained the heat of the oxyhydrogen blow-pipe he would inevitably have ignited the atmospheric nitrogen and burnt up the whole of the atmospheric oxygen. The combustion would have been propagated from particle to particle, had not the igniting point been higher than the temperature produced by its combustion. The union of the two gases which compose the air must have resulted from this ignition at a single point; but as the igniting point is higher than the temperature produced by the combustion of the nitrogen, the combustion of atmospheric air cannot be communicated from one point to another, but can only go on where the temperature is sufficiently high. The temperature of an ordinary fire is not sufficiently high for this purpose. It does not exceed about 4000° Fahr. The temperature of our ordinary oil, gas, and candle flames does not exceed about 3500° Fahr. The igniting point of nitrogen is considerably above that. It is impossible to measure these high temperatures, but I have calculated from an experiment with a mixture of oxygen and nitrogen, that a temperature of about 5400° is necessary to ignite nitrogen. Now, you see the temperature we have in a common fire, and that which we have in common gas and candle flames, are not sufficient for the ignition of nitrogen, and therefore we get no combustion of nitrogen in these flames—a circumstance which, as we shall presently find, is of great value to us, and contributes considerably to the comfort of our lives. We should have exceedingly noxious effects produced in the atmosphere by the ignition and combustion of nitrogen with oxygen. We have, however, some sources of heat sufficient to ignite nitrogen. One of these sources is the combustion of oxygen and hydrogen gases in the proportions to form water, or nearly so. If we mix these gases with nitrogen, and then ignite them, and add at the same time a certain excess of oxygen, the nitrogen burns,—to a limited extent it is true,—but it undergoes very definite combustion.

The temperature of the electric spark is also high enough to ignite nitrogen, being above the igniting point of that gas; and consequently if we pass a stream of electric sparks through a jar of atmospheric air, such as we have here, we shall have an ignition of the nitrogen which it contains, and its combustion at the expense of the atmospheric oxygen. You see at the present moment [exhibiting a glass flask containing air] this is quite colourless. If the nitrogen burns on the passage of the electric sparks, it will produce ruddy vapours in the flask. You will see, in the first place, a yellowish colour, and, finally, a reddish colour, produced by the action of the stream of electric sparks, as they pass between these two points. [A series of electric sparks from a Ruhmkorff's coil was then passed through the flask of atmospheric air.] We shall only get our colour after some time; but it is an experiment which is worthy our seeing, we shall therefore wait. Oxidation of the nitrogen is caused by the passage of the electric sparks through the jar, and consequently such an oxidation must take place every time a flash of lightning passes through the atmosphere.

Nitrogen in thus uniting with oxygen, forms an extensive series of compounds. Here we have a list of them in this table:—

Compounds of Nitrogen with Oxygen.

Protoxide of Nitrogen . . .	N O
Binoxide of Nitrogen . . .	N O ₂
Hyponitrous Acid . . .	N O ₂
Nitrous Acid . . .	N O ₃
Nitric Acid . . .	N O ₅

In any proportions in which the oxygen does not exceed two equivalents to one of nitrogen, the compound obtained is neutral; when there is a larger proportion of oxygen than this, the compound becomes acid.

We have already a very perceptible yellow colour-

ing produced in that flask [through which the electric sparks were still being passed]; and in the course of a minute or two more, I dare say it will be more perceptible. The compounds produced here are the three last mentioned in the table to which I have just directed your attention. They consist partly of hyponitrous acid, partly of nitrous acid, and partly of nitric acid. All these three substances are liable to be formed in this way; and in the action of lightning in thunderstorms these three compounds are produced, but the two compounds containing the smaller proportions of oxygen gradually pass into the last containing the highest proportion of oxygen; and therefore it is that we usually find present in the rain that descends after a thunder-storm a certain proportion of nitric acid.

We have now a very decided brown [again referring to the flask through which the sparks had been passing]. The operation is a very slow one, but the formation of these oxides of nitrogen continues to increase.

This is one source, then, of the fifth combination of nitrogen with oxygen—nitric acid, which we have next to consider. It is produced by the combustion of atmospheric nitrogen, and it is also found in a state of combination with bases. It forms nitrates with bases. Some chemists are of opinion that all the nitric acid which we meet with in combination with potash or soda, in the so-called "nitre districts," is due entirely to the putrefaction and decay of animal and vegetable substances; while others contend that it is due to the combustion of nitrogen by atmospheric electricity. Probably the proportion of nitric acid generated in the atmosphere, and present in the rain in this way, is comparatively small; and we find our chief supplies of this substance from the oxidation of nitrogen contained in animal and vegetable substances, but especially in animal substances. Now, nitrogen which is already combined is capable of undergoing this kind of combustion at the ordinary temperature of the atmosphere. It is going on around us, in fact, in the soil of London. Permeated as it is by the sewerage, we have there animal matters containing nitrogen undergoing this process of combustion with oxygen without any elevation of temperature whatever, producing immense quantities of this substance, nitric acid, which may be detected in all the shallow wells in and around London. It is especially abundant in the neighbourhood of burial grounds, where animal matter is oxidizing to a greater extent than it is in other localities; and the wells in those neighbourhoods have been found to contain a large proportion of the salts of nitric acid.

Nitric acid may be made by a process such as we have proceeding here. It is here being obtained by displacing it from its compounds with bases by means of sulphuric acid. We have added a quantity of sulphuric acid to this nitrate of potash, or common nitre, which is one of the best known salts of this body. Sulphuric acid is capable, under the influence of heat, of displacing the nitric acid. After the reaction we shall have left sulphate of potash in the retort, whilst nitric acid distils over.

Nitric acid thus obtained is a colourless, fuming, limpid, highly corrosive liquid, and contains one equivalent of nitrogen and five equivalents of oxygen, which we have represented on the diagram by the symbol NO₅, but our nitric acid contains also one equivalent of water. It is distinguished for its powerful oxidizing properties. It oxidizes metals with very great facility, converting them, first, into oxides, and, subsequently, into nitrates. Here is some of this acid which is used commercially on a large scale, being formed by this decomposition which we have going on here. The operation is performed in large cylinders which are lined with fire bricks in order to protect them from the action of the acid. If nitric acid is brought into contact with copper a very powerful oxidation of the copper takes place, with the production of

these red fumes. These red fumes are the same as those which we have been forming in this flask, only you see here they have a greater intensity. Here is a greater amount of this red compound produced by the deoxidation of this nitric acid. It is from this deoxidation of the final compound of nitrogen and oxygen that we usually obtain our supplies of the other compounds of nitrogen and oxygen. We might perform the same experiment, also, with iron, which is oxidized in the same way and gives rise to the same red fumes. Nitric acid, however, is incapable of oxidizing all the metals in this way. If we bring it in contact with gold, for instance, no such oxidation occurs. [A piece of gold leaf was placed in a glass vessel containing nitric acid.] The gold floats about in the nitric acid with its brilliancy unaffected. It is also incapable of oxidizing platinum and a few other metals; but the great majority of metallic substances are capable of being oxidized by it. These oxides, being taken up by the remaining nitric acid present, form nitrates, and thus we produce our nitrate of copper, nitrate of iron, nitrate of zinc, and nitrates of other metals which we wish to obtain.

Nitric acid may be very readily detected by this very process that we have been performing here,—namely, by deoxidizing it by means of copper turnings. If we first set the acid free from any combination in which it may previously have existed, by the addition of sulphuric acid, as we have done here, and then bring copper turnings into contact with the liquid in which the nitric acid is thus set free, we have these red fumes produced which are quite characteristic of the presence of nitric acid. When the quantity operated upon is small, we may not, perhaps, perceive any of these fumes: in this case we can detect the presence of the nitric acid by those papers we employed on the last occasion for another purpose. Here are some papers which have been immersed in a mixture of starch and iodide of potassium, and you see they are powerfully acted upon by this gas; the action is, indeed, too powerful for you to see it properly. They are browned very strongly, but with a smaller quantity the paper is rendered blue. You see this bluing action better when the paper is moistened a little.

Now, you will remember that this is precisely the test which is used for the detection of ozone in the atmosphere. We mentioned it in the last Lecture, as being used to show the presence of ozone in the atmosphere, and we have seen that every electric spark that passes through the air produces this acid. How, then, can this be a proper test for the presence of ozone in the atmosphere? If we know that this nitrous acid produces the same effect upon the papers as was produced by what is supposed to be ozone, how can such papers be said to be a test for ozone? It is obviously quite unreliable. The effect would be produced, and I think probably is produced, by the nitrous acid derived from the passage of electric discharges through the air, and not by ozone at all.

From nitric acid we can obtain, by graduated deoxidation, the remaining compounds of nitrogen with oxygen. The first compound resulting from the gradual deoxidation, is nitrous acid, and the next is hyponitrous acid, which contains three equivalents of oxygen and one of nitrogen; the next compound which we shall come to, will be the so-called "binoxide of nitrogen," which contains two equivalents of oxygen and one equivalent of nitrogen. This is the substance which is produced when nitric acid is acted upon by copper turnings; in fact, we had it produced in the first experiment. In order to obtain this substance, NO_2 , it is necessary to exclude the air; and here is an apparatus by which we can perform that experiment. The operation shall be going on while we are endeavouring to make ourselves acquainted with the properties of this gas. Here we have a vessel containing copper turnings. We pour a portion of nitric acid through this funnel-shaped tube, which passes nearly to the bottom of the jar. The

gas, on being evolved, will pass out through this flexible tube, and be collected here, [referring to a jar inverted over the pneumatic trough.]

Binoxide of nitrogen is a perfectly colourless and transparent gas, like those we are already acquainted with. Here is a jar of it, for example, which has been already collected, and in which we shall be able to see some of its properties. It possesses a specific gravity only slightly greater than that of air, very slightly indeed, it being 1.04. It is slightly soluble in water, water absorbing about 5 per cent. of this gas; but still we can collect it over water without any material loss; that is, in fact, the mode in which this gas is generally collected. One of its most distinguishing characteristics is its strong affinity for a further amount of oxygen; it is, indeed, a chemical compound in a very unstable position, and it has a great desire for a further quantity of the element oxygen. If we press some of this gas up into a jar containing oxygen, we shall find that it will at once produce those ruddy fumes that we had formed here, owing to the transformation of the binoxide into the next two compounds below it on the diagram—hyponitrous acid and nitrous acid. Here, for instance, is a jar half filled with oxygen, [the jar of binoxide of nitrogen was discharged into the jar of oxygen standing in the pneumatic trough.] You see where it comes in contact with the oxygen, these dense red fumes are produced, and you will notice after a very short time, that there is a considerable absorption of the red compound in the interior of the jar. You see how the water is rising in the interior of the jar taking the place of the gas which it absorbs. These two compounds, hyponitrous acid and nitrous acid, which were produced by the addition of the oxygen to the binoxide of nitrogen, are both of them very soluble in water, and are, therefore, very rapidly removed from the remaining oxygen present in the jar.

Binoxide of nitrogen presents a rather remarkable character in regard to combustibles. It is difficult to say whether it is a supporter of combustion or not. It is not inflammable, at all events; we can affirm that of it positively; and if we plunge a taper into this gas, you see the light is immediately extinguished, so that we should be rather inclined to conclude from that experiment that binoxide of nitrogen does not support combustion; and perhaps we should be quite right in that conclusion. The fact is, that unless the burning substance we place in the binoxide has sufficient heat in it to decompose the gas, transforming it into its elements, oxygen and nitrogen, the combustion is not supported. If, however, the combustible can decompose the gas, it will continue to burn in the mixture of nitrogen and oxygen which is formed. Phosphorus, for instance, is a substance of this kind. If we put a fragment of phosphorus into this jar of binoxide of nitrogen, if it is only just ignited the temperature of the phosphorus is not enough to decompose the gas; but if actively in combustion it continues to burn in the gas with very considerable brilliancy, especially after the phosphorus vapourises, and thus comes into extensive contact with the binoxide. But it is not in the binoxide itself that the phosphorus burns, because if we introduce it in only a languidly ignited state, it is extinguished. Another substance which is capable of burning in this gas is the bisulphide of carbon, which we have already used in a former experiment. Here is our jar of binoxide of nitrogen; here is our bisulphide of carbon. We will pour a little bisulphide of carbon into the jar and agitate it a little, so that the vapour may mix pretty well with the gas. [A light was applied to the mouth of the jar, and a slight explosion, accompanied with a bright flash, took place.] This substance, you see, undergoes very brilliant combustion in the binoxide. The temperature of its combustion is sufficient to decompose the gas, and then the vapour of the bisulphide burns in the mixture, which contains an equal quantity of oxygen and nitrogen, and

is, therefore, much richer in oxygen than atmospheric air. The bright light contains also a large amount of what have been called the "chemical rays," and therefore it has been used in photography. It enables you—in the dark, I was going to say—at all events, without sunlight, to take photographic pictures.

Now, the remaining compound of nitrogen with oxygen—namely, the protoxide—is obtained by a still further reduction of nitric acid, by which we remove a further quantity of its oxygen. This protoxide is a compound in itself unimportant, but it is rather singular in its effects. It is remarkable for its peculiar effect upon animals, and on this account it is called "laughing gas." If I could exhibit some of its effects before you, I should then consider myself justified in speaking longer about it; but as we cannot very well do that, I think we had better pass it by simply with the remark that it resembles the binoxide with regard to combustibles. Some substances will not burn in it. Sulphur, for instance, is at once extinguished; therefore we can say of all these gases that they do not support combustion when the oxygen is in combination; but if they are decomposed by the heat of the combustible, the products of their decomposition, nitrogen and oxygen, do exert a supporting effect upon combustion.

We now come to the compounds of nitrogen with hydrogen,—namely, ammonium and ammonia,—the respective compositions of which are represented here on the diagram:—

Compounds of Nitrogen with Hydrogen.

Ammonia, or ammoniacal gas	NH_3
Ammonium	NH_4

These substances can neither of them be formed by direct combination with their elements. It requires indirect means in order to bring about these combinations. Both of these bodies are produced by the gradual decay or putrefaction of organic substances. Ammonia uniting with acids, or even with water, give rise to ammonium. But this ammonium is a somewhat hypothetical body. We have never as yet been able to get it in a free state. It is contained in chloride of ammonium, which is obtained by neutralising hydrochloric acid by ammonia. Chloride of ammonium contains one equivalent of ammonium united with one equivalent of chlorine. We might go a little farther than that, and form a kind of alloy, or amalgam, with this hypothetical substance, ammonium, by making it combine with mercury. Such an amalgam is produced when we act upon a solution of chloride of ammonium in water by an amalgam of sodium and mercury. The two metals, potassium and sodium, are capable of extracting the chlorine and leaving the ammonium disengaged from the chlorine. But the ammonium does not appear in a free state. It combines, upon the moment of its liberation, with mercury, and forms a kind of pasty amalgam, which reminds us of the amalgams formed by dissolving tin, zinc, lead, and other metals, in mercury. Here we have some amalgam formed with sodium and mercury, and I will pour some of it into this vessel [a shallow white dish], which contains a solution of chloride of ammonium. Now, you see this mass which I poured into that was not very large, but it is growing very considerably. It has nearly filled the lower part of the dish, and it has now changed its character. It is so light that it is floating upon the surface of the liquid here; and you see it forms a kind of butter-like mass which is capable of being moulded into any form, and taking a very high polish. Here we have some of this body forming in a tall jar, and you may there see it grow more clearly than in this basin. You see from that comparatively small portion of material what an immense mass of this butteraceous substance we have produced.

The other body, ammonia, is readily produced from chloride of ammonium, which we obtain from the destruc-

tive distillation of animal and vegetable substances. Gas liquor, obtained in the manufacture of coal gas, and bone liquor, furnish us with a great bulk of the ammonia contained in this chloride of ammonium. If we mix chloride of ammonium with quick lime or, better, with hydrate of lime—slaked lime—we remove from it the chlorine, and also one equivalent of the hydrogen which it contains, and we have then evolved, in the form of gas, ammonia or ammoniacal gas as it has been called with greater propriety. Here is some of it coming off; we will collect it at once, into this vessel containing water where it will be absorbed, and we shall obtain a solution of it. We have some of this gas already collected here in these jars; here is a jar of it, so that from this we can ascertain sufficient of its properties for our present purposes. It possesses a specific weight much less than that of the atmosphere; it is, bulk for bulk, about half the weight of atmospheric air, its specific gravity being about .539. It cannot be respired in its concentrated form; if diluted with air and then respired it has rather exhilarating and pleasant effects than otherwise. It is the volatile gaseous matter which comes out of those Preston salts bottles which are pretty generally known, and which are found to be sometimes refreshing. Under these circumstances it is of course highly diluted with air. Ammonia is slightly inflammable, but you saw that it was necessary, in the experiment where we burnt ammonia in the previous part of the Lecture, first to heat it above its igniting point in order to have a continuous combustion. It is one of those gases which can be rendered liquid by pressure. It is a highly alkaline substance, and this is at once rendered evident if we dissolve some of it in a reddened solution of litmus. Here, for instance, is a solution of reddened litmus in water, by means of which we will absorb this jar of ammoniacal gas. [The mouth of the jar containing the ammonia was placed in the reddened solution, and upon the removal of the stopper beneath the surface of the liquid the water rushed up and filled the jar.] You see how rapidly it is absorbed by water and how the red colour of the litmus solution, which we employed for the purpose of showing that ammonia is alkaline, was transformed into blue when the liquid came into contact with the gas. Water in this way is capable of absorbing no less than 780 times its volume of this gas.

We must now rapidly pass on to commence, at all events, the history of another element, namely, Carbon, which exists in three forms in nature; namely in the form of diamond with which we are all acquainted; of graphite, which we know in those lead pencils used for marking upon paper; and in the form of charcoal as it is obtained by heating animal and vegetable substances to redness. These substances are all of them essentially the same element, and they produce on their combustion precisely the same compound. We will endeavour to burn three specimens of these substances, namely, diamond, graphite, and charcoal, and ascertain whether the substance produced is really the same in each case, and by that means establish the identity of the three substances. We will first endeavour to burn a diamond. This small piece of diamond is embedded in plaster of Paris in order to hold it conveniently. In order to burn it it is necessary to heat it to a very high temperature, and as its igniting point is very high, I shall require to light it in a jet of hydrogen in contact with oxygen. You see we have here a jar of oxygen, and when we have ignited the diamond to a sufficient temperature, we will plunge it into this jar, and then I hope it will continue its combustion. It will certainly do so unless we have not heated it sufficiently; but the experiment is rather difficult, unless we take a large diamond, and then it becomes rather a costly experiment. [The diamond was ignited by means of the oxy-hydrogen blow-pipe.] There, our diamond has got up to a white heat. [The diamond was then introduced into the jar of gas.] There is our diamond, burning

as a bright point in the jar of oxygen, and when it has burned a little longer so as to give us an appreciable quantity of carbonic acid—for it burns very slowly—we will test whether we have really produced carbonic acid by this combustion of the diamond. Now, we will take, in the same way, a piece of graphite; in fact, a piece of a Mordan's pencil, and burn it in another similar jar of oxygen. In the meantime we will make sure that this is the jar in which the diamond was burned. Now, I think we shall not find so much difficulty with our graphite in getting it up to the proper temperature. You see that burns more readily than the diamond does; we have not to heat it to so high a temperature, and now it is introduced into the oxygen combustion goes on much more rapidly. The combustion will be very much sooner extinguished, although we have a quantity of graphite, five or six times the weight we had of the diamond. Sufficient carbonic acid has now been produced to make its presence manifest. Finally, we will take a piece of charcoal, which will not require to be heated much. [A piece of charcoal was burned in a jar of oxygen.] You see what a wonderful effect cohesion has upon this chemical process. There we had such difficulty in igniting our hard and compact diamond; we had less difficulty in igniting our graphite, which was less dense than the diamond; and, finally, we had no difficulty in igniting the charcoal. Now, let us see whether we have precisely the same product produced in all these instances. Here is some lime-water which we shall find to be a most delicate test for carbonic acid, and I will pour a little of it into each of these jars. [A quantity of lime-water was poured into the three jars in which the diamond, graphite, and charcoal had been burned.] There, you see, we have produced a quantity of chalk; we have formed carbonic acid from the combustion of that diamond; the carbonic acid has united with the lime, forming the carbonate of lime or chalk. Here is the result of the combustion of the graphite which is identically the same; and in the jar in which the charcoal was burned we have also carbonate of lime precipitated, showing the production of carbonic acid in that jar; so that here we have precisely the same result in all three cases.

NOTICES OF BOOKS.

On the Composition of Oxen, Sheep, and Pigs, and of their Increase whilst Fattening. By J. B. LAWES, F.R.S., and Dr. J. H. GILBERT, F.R.S.

THE pamphlet which has recently appeared under this title sets forth the results of an extended series of analytical experiments in continuation of those already communicated by the same authors to the Royal Agricultural Society. The object has been, in the present instance, to investigate the nature of the increase, and the relative development of the different organs or parts of fattening animals under various conditions of feeding. As a process of "meat manufacture," therefore, where the value of raw materials and the proportionate yield of saleable carcasses have to be considered, the question directly addresses itself to the agriculturist, constituting, indeed, a highly important branch of the business of the farmer; and to the chemist opens up a wide field for investigation in reference to the disposal in the animal economy of the several constituents of food,—to what extent they contribute directly to the formation of flesh,—and what proportion is necessarily lost in the form of offal and waste, or as products of inferior commercial value.

A diligent study of the numerous Tables in the original treatise is requisite to place the inquirer in the full possession of the details of an investigation

so laborious as that undertaken by Messrs. Lawes and Gilbert. The experimental results are drawn up for comparison, and exhibited in twenty-one tabular statements. In these columns the quantity and nature of the food consumed, with the gross increase resulting therefrom,—the proportion subsisting between the several parts of the animal,—the distinctions of offal and carcass,—and (in pigs) the relation of fat to lean, are conspicuously stated. Then, in regard to the chemical composition of the parts of the animal, the distinctions of fatty, nitrogenous, and mineral constituents and water, are deduced from means of several individuals in each class. And, lastly, the increase of the animal whilst fattening is referred, in like manner, to the several constituents of the food consumed.

The main conclusions from the whole inquiry may be briefly enumerated as follows:—

I. Food and Increase.

Fattening oxen fed liberally upon good food, composed of a moderate proportion of "cake" or corn, some hay or straw chaff, with roots, or other succulent food, and, well managed, will, on the average, consume from 12lbs. to 13lbs. of the dry substance of such mixed food per 100lbs. live-weight per week; and should give 1lb. of increase for 12lbs. to 13lbs. of dry substance so consumed.

Sheep fattening, under somewhat similar circumstances, but with a less proportion of hay or straw, will consume about 15lbs. of the dry substance of the mixed foods per 100lbs. live-weight per week, and should yield, over a considerable period of time, 1 part of increase in live-weight for about 9 parts of the dry substance of their food. If the food be of good quality, oxen and sheep may give a maximum amount of increase for a given amount of total dry substance of food, even provided the latter contain as much as 5 parts of total non-nitrogenous to 1 of nitrogenous compounds.

Pigs fed liberally upon food composed chiefly of corn, will consume from 26lbs. to 30lbs. per 100lbs. live-weight per week of the dry substance of such food. They should yield 1 part of increase in live-weight for 4 to 5 parts of the dry substance of the food. They may give a maximum amount of increase for a given amount of dry substance of such food, if it contain as much as 5 or even 6 parts of total non-nitrogenous to 1 of nitrogenous compounds.

Taking into consideration the cost of the foods and the higher value of the manure from those which are rich in nitrogen, it is frequently the most profitable for the farmer to employ,—even up to the end of the feeding process,—a higher proportion of nitrogenous constituents in his stock-foods than is necessary to yield the maximum proportion of increase in live-weight for a given amount of dry substance of food.

II. Proportion of Parts.

In proportion to their weight, sheep yield rather more internal loose fat than oxen, and pigs very much less than either.

As oxen, sheep, and pigs mature and fatten, the internal organs (offal parts) increase in actual weight, but they diminish in proportion to the weight of the animal.

Well-bred and moderately-fattened oxen should yield about 60 per cent. carcass in fasted live-weight, and sheep in similar condition a like amount. Excessively fat oxen may yield from 65 to 70 per cent. carcass.

When the fattening food of oxen, sheep, and pigs contains less than about 5 parts of non-nitrogenous to 1 of nitrogenous compounds, the proportion of gross increase for a given amount of dry substance of the food will not increase with the increased proportion of nitrogenous compounds; the proportion of carcass to the live-weight will probably be somewhat less, and the carcasses themselves will be somewhat more bony and fleshy, and less fat.

III. Chemical Composition of the Animals.

Of dry fat the entire body of a fat calf contained about

14½ per cent.; of a fat ox, 30 per cent.; of a fat sheep, 35½ per cent.; and of a moderately fat pig, 42 per cent.

In the fattened condition, the entire bodies of calves and oxen will probably contain about 4 per cent. of mineral matter; those of lambs and sheep, under 3 per cent.; and those of pigs, on an average, 1½ per cent.

This mineral matter may generally be reckoned to contain nearly 40 per cent. of phosphoric acid, and about 6 per cent. of potash.

The mean composition of six animals analysed in a condition fit for the butcher shows about 3 per cent. mineral matter, 13 per cent. nitrogenous compounds, and 33 per cent. fat; in all, about 49 per cent. total dry substance, and 51 per cent. water.

The proportion of mineral matter in the bodies of oxen, sheep, and pigs rises and falls with that of the nitrogenous compounds.

IV. Composition of Increase.

The increase of liberally-fed oxen over the last six months of the fattening period will probably consist of 70 to 75 per cent. total dry substance, of which 60 to 65 parts will be fat, 7 to 8 parts nitrogenous compounds, and about 1½ part mineral matter.

V. Relation of Constituents in Increase to Constituents Consumed.

Sheep fattening for the butcher on a good mixed diet will seldom carry off more than 3 per cent. of the consumed mineral matter. They will probably carry off less than 5 per cent. of the consumed nitrogen, if the food be comparatively rich, and more than 5 per cent. if it be comparatively poor in nitrogen. They should store up about 10 parts of fat for every 100 parts of non-nitrogenous substance consumed.

Pigs liberally fed on fattening food should store up 20 parts, or more, of fat for every 100 parts of non-nitrogenous substance consumed. These animals were found to store up four or five times as much fat as was supplied ready formed in their food.

If the produced fat were formed from starch, about 2½ parts would be required for the formation of 1 part of fat. In the sense here supposed, if the fat were so formed, about two-thirds of the dry substance of the food would be expired, perspired, or voided, without directly contributing to increase.

The comparative values of our current fattening food-stuffs, as a source of saleable animal increase depend more on their amount of digestible and assimilable non-nitrogenous than on that of the nitrogenous constituents; but, as a source of manure, their value will be the greater the higher their proportion of nitrogenous compounds.

Such are the main points which the authors deduce as the result of their observations. In reviewing these, we are willing to allow that many of the conclusions appear to be fully borne out by the experimental and numerical data urged in their support, and are, moreover, in general accordance with popular opinion. The relation of parts in the animal, and their average rate of increase, would, doubtless, be considered as established on sufficient basis. There are some points, however, to which we should be disposed to take exception, partly by reason of what may be termed the superfluous manner of employing and stating the results. Thus, in Table V., in the last column, are given the absolute weights of the carcass and the several internal organs of the sheep, calculated as a mean of 249 individuals; yet to furnish this mean, or average, 5 sheep in the lean (store) condition are included with 45 others excessively fat; and we find, in consequence, that the item "caul fat," which is shown to vary in the sheep from 2½ lbs. to nearly 10 lbs., according to the condition of the animal at the time of slaughter, is brought out, nevertheless, and made to give a general mean in the last column. The expediency of taking so many as 100 sheep to furnish an average for the "moderately fattened" is, we think, a little questionable.

In reference to the chemical composition of the animal bodies, in their entirety and as separate parts, it is to be regretted that no particulars are afforded explanatory of the analytical methods employed and of the general system of operating. We are not informed whether, for instance, the whole organ (and frequently no less would be satisfactory) was consumed in an examination for mineral constituents; in what manner the relative proportions of nitrogenous and non-nitrogenous matters were estimated. These and other questions suggest themselves as difficulties in the working of chemical processes on a scale sufficiently extensive to ensure trustworthy results. That the authors are themselves fully prepared to admit the difficulty of an investigation such as that attempted is evident, among numerous references, from the paragraph with which we conclude this notice:—

"The results must, indeed, be looked upon as only approximations, though we believe the data now supplied constitute the most reliable basis for estimates of this kind at present at command."

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Iron and Nitride of Iron.—By passing a galvanic current from a Daniell's battery through a pure solution of chloride of iron H. Kramer obtained (*Chemisches Centralblatt*, No. 18, April 24, 1861), on the kathode a thin coating of metal, which easily took a bright polish. On increasing the strength of the current, so that hydrogen was freely evolved, he procured the reduced iron in a spongy mass so soft and porous that it could be flattened to a thin plate by the pressure of the thumb-nail.

The mass reduced by Bottger's method from a mixed solution of protosulphate of iron and sal ammoniac is very different. It is as hard as steel and as brittle as glass, and on examination is found to be not pure iron but nitride of iron. If this mass be rubbed to powder, which its brittleness easily permits, and then is washed until the washings no longer give any precipitate with a silver solution, it still yields when heated with soda-lime, an alkaline gas, which gives a white precipitate when passed into a solution of chloride of mercury. One gramme of the mass gave 1.420, and in a second experiment 1.421, of peroxide of iron, which makes the proportion of nitrogen contained 1.49 per cent. The author thinks that this proof of the ease with which nitrogen combines with iron is confirmatory of Fremy's views of the chemical constitution of steel, and also Schafhaüt's on the composition of English white iron.

A Double Salt of Chloride of Calcium and Carbonate of Lime.—In making a solution of commercial chloride of calcium, Fritzsche observed (*Bulletin de St. Petersburg*, tome iii. p. 285) that a small quantity of sandy powder remained undissolved. As long as the solution of the chloride was concentrated, this powder had a yellowish appearance, but on diluting the solution it became white. On searching for the cause of this change in appearance, the author found that the powder was composed of crystals of a double compound of chloride of calcium and carbonate of lime, and that the alteration in appearance was owing to a decomposition effected by the water. Some of the crystals placed on a glass plate with a little water, and examined immediately by the microscope, were seen at first to be perfectly transparent; but soon the surfaces became cloudy, and a granular separation was apparent. In consequence of the solution of the chloride of calcium they soon lost all their transparency, and after a time there only remained a skeleton of carbonate of lime of the size and shape of the original crystals. Some of the sandy powder separated very carefully from the chloride of calcium was found on

analysis to have the composition $\text{Ca Cl} + 2\text{CaO CO}_2 + 6\text{HO}$.

II. ORGANIC CHEMISTRY.

A New Acid by the Oxidation of Nitro-Benzene.—When nitro-benzene is oxidised by boiling either with a solution of permanganate of potash or a mixture of nitric acid and bichromate of potash, there is found among the products a peculiar acid. The oxidation is most conveniently effected by the last-mentioned means, but care must be taken to have an excess of nitro-benzene. The new acid is soluble in hot nitro-benzene, but separates on cooling in small white crystals, which remain suspended in the solvent. This is separated by decantation, and is then shaken up with an excess of ammonia, which dissolves the new acid and another, forming a deep yellow salt much like picric acid in appearance. The solution is treated with hydrochloric acid, which causes the new acid to deposit. It is then washed with distilled water to remove chloride of ammonium and also some yellow acid which accompanies it. So purified, it has the following properties:—It is colourless, has a sharp, slightly bitter taste, and presents itself in slender needles irregularly grouped together. It fuses at a temperature little above the ordinary, and completely volatilizes, condensing in well-formed brilliant needles. Almost insoluble in cold water, and but little soluble in boiling water, it dissolves freely in alcohol, ether, and nitro-benzene. It dissolves, also, in hot acetic acid, and crystallises out again on cooling. Several analyses of specimens prepared by different methods led the authors (M.M. Cloez and Guignet, *Bulletin de la Société Chimique de Paris*, No. 1, p. 3) to the following as the formula of the new acid:— $\text{C}_{10}\text{H}_7(\text{NO}_4)\text{O}_6$, and induce them to regard it as a product of the oxidation of nitro-cinnamic acid $\text{C}_{10}\text{H}_7(\text{NO}_4)\text{O}_4$. In conclusion, they remark that they have experimented with commercial nitro-benzene, and the new acid may come of the oxidation of some foreign body in that article.

Preparation of Aniline Red by Arsenic Acid.—We may add the following (*Polytechn. Centralblatt*, 1861, s. 493) to the account we gave of this process at p. 292, vol. ii. It seems that if an excess of aniline be employed no result is obtained until this excess has distilled over. If, on separating this colour afterwards, it is found to be contaminated with tarry matter, it is best removed by mixing the whole with sand, and then adding a little hot water, and filtering. Sometimes it happens that the dyer fails in using aniline red, because the fuchsine has got combined with ammonia. In such a case the addition of a little acetic or any other acid will make the bath again available. Gerber-Keller (*Ibid.*, s. 398) has repeated Dr. Hofmann's experiments on the action of bichloride of carbon on aniline (See *CHEMICAL NEWS*, vol. ii. p. 292) with exactly the same results. He obtained an oily or doughy mass, which in time changed into a hard, brittle product, according to the temperature and strength of the action. Between 180° and 195° the author obtained in every experiment with Hofmann's process a magnificent crimson-red dye, which is without doubt identical with the Fuchsine of M.M. Verguin and Rénard, Brothers. The chloride of carbon acts on aniline, but very slowly,—even at high temperatures,—while the production of azaleine with certain easily-reducible oxygen salts takes place in a few hours. Dollfus-Galline confirms the foregoing, but remarks that the colour prepared by Hofmann's method has a yellowish tone. In general, he says, the aniline reds made with chlorine compounds have a vermilion tint, while those prepared with oxygen salts have a violet. Gerber prepares his azaleine at a temperature which never exceeds 109°C . In Hofmann's method 200° must be employed, but this need be no obstacle to its technical application. The author thinks it probable that a purer red may be obtained by this than by any other process.

MISCELLANEOUS.

SACRIFICIAL METALS.

A curious statement made in the House of Commons, a few days ago, induces us to offer a few remarks on what may be called, appropriately enough, "the sacrificial function in metals." It was stated, our readers will remember, that the leaden envelope with which the Armstrong shell is surrounded, and which is absolutely necessary as a constituent part of that missile, might be caused to adhere securely, either by "a sort of mortise" or by the intermediation of zinc. The second expedient is that indeed adopted; with what amount of success the recent practice of these guns in China would disclose, were the Government not so pertinaciously bent on holding back the communications which have reached them on this matter.

It is a fact perfectly well known to chemists, but one which mechanicians have not heeded nearly so much as it deserves, that when two metals are retained in contact, and conjointly exposed to chemical influences during long periods of time, one metal sacrifices itself to ensure the other's preservation. The history of mechanical construction furnishes numerous illustrations of this chemical fact, as will be presently seen, when we come to cite a few examples; the marvel, then, is, that Sir William Armstrong—or, rather, the laboratory branch of the War Department, before whose cognizance the proposition of zinc soldering (thus to designate it) must have come—could ever have sanctioned an expedient which must necessarily fail in the end, like every other expedient which violates a law of nature. The history of ships' copper sheathing shall be taken as our first illustration of the sacrificial metallic function. Sir Humphry Davy, as is well known, devised a method of checking, or altogether obviating, the destruction of ships' copper sheathing. He accomplished this by attaching to the ship's bottom, at suitable intervals, slabs of the metal zinc, and which he called protectors. Protectors they were, in the following manner:—The zinc rapidly corroded, and was lost; but, so long as any zinc remained for the sea-water to act upon, the copper remained untouched. So far as copper preservation is concerned, the method adopted must be pronounced efficient. Practically, it failed, indeed, to secure the advantages described, but not for any reason that concerns us here. It was found that when copper no longer slowly dissolved, it ceased to be a poisonous metal. Barnacles and sea-weed attached themselves, just as they might have done to an uncoppered wooden bottom; and, moreover, owing to a galvanic action set up, the ship's copper was rapidly fouled by a deposition of magnesia and lime, precipitated from the magnesian and calcareous soluble salts always present in sea-water. Failing, then, to achieve what was intended of it, the copper-protecting process of Davy ceased to be employed; but the failure of it is that which alone concerns us here, as illustrating what we would wish to convey by the words "sacrificial metal."

Take, as the next example, the illustration afforded by the setting of an iron paling-rail in a bed of lead. The most casual observation, as one passes along the streets of this city, may be made more pregnant with fact bearing upon this matter than the longest homily. For a time, varying as to length with locality, external influences, and—perhaps, in some degree—on the varying quality of the iron and lead brought into contact, both metals remain sound. But, after a time, decay inevitably sets in, and, when once commenced, marches to the issue of final destruction with wonderful rapidity. The remarkable fact is, that both metals do not decay simultaneously; it is the iron which corrodes, whilst lead—the softer metal—

remains intact. Let the mechanic do what he will, this result cannot be prevented—a law of nature having decreed the sacrifice, it must and will be achieved.

Our next illustration shall be ordinary tin plate—iron, coated with tin, as is well known. Well, what sort of destruction is set up when tin plate has been exposed for a long duration of time to the atmosphere? Is the tin destroyed—does it tarnish even? Never. Iron is the sacrificial metal here; and, as surely as the iron is anywhere exposed, it perishes, crumbles, and dissolves away, with destructive rapidity. The rate of destruction of iron totally unprotected is slow, by comparison with that which ensues when, owing to a flaw or disintegration of the covering tin envelope, atmospheric agencies come into play upon the underlying metal.

But the case we most particularly wish to direct attention to, is the result of bringing zinc into contact with iron, and retaining the two metals together over long periods, as may be seen in the so-called galvanized iron. Under this latter disposition, zinc becomes the sacrificial metal. Not one particle of iron decays, so long as atmospheric destructive agents can wreak their dissolution—so to speak—on the protective zinc. Nor does this protection altogether depend on a complete covering of the iron. Flaws and imperfections there are, and necessarily must be, through which, quite down to the iron, destructive agents, always present in the atmosphere, must penetrate. They do not act upon the iron, nevertheless, so long as a sufficient expanse of protective zinc surface remains; and this simply because a fundamental law of nature forbids their doing so.

Now, if our remarks be true—and we are content to appeal to chemical science for a verdict—what becomes of the efficiency claimed for the Armstrong shell-envelope, because of the attachment of lead by a process of zinc soldering? Sound, to the eye, these projectiles may at first seem; but a disruptive force will be acting upon them, nevertheless, from the very beginning; and in total ruin and destruction this force will eventuate at last; whatsoever Sir William Armstrong's advocates may assert, notwithstanding—whether at Elswick or at Woolwich, whether in Parliament or out of it.—*Mechanics' Magazine*.

Royal Institution.—The following is the arrangement of Lectures for the ensuing week:—Tuesday, May 14, at 3 o'clock, Mr. John Hullah, "On the History of Modern Music." Thursday, May 16, 3 o'clock, Mr. W. Pengelly, "On the Devonian Age of the World." Friday, May 17, 8 o'clock, Professor J. Clerk Maxwell, "On the Theory of Three Primary Colours." Saturday May 18, 3 o'clock, Professor Max Müller, "On the Science of Language."

Chemical Society.—The next meeting of this Society will be held on May 16, when there will be a discourse delivered by W. H. Perkin, Esq., "On the Colouring Matters obtained from Coal-tar."

Royal Institution of Great Britain.—At the General Monthly Meeting, held on Monday, May 6, 1861, Sir Henry Holland, Bart., M.D., F.R.S., in the Chair, the Hon. Lieut.-Gen. Thomas Ashburnham, C.B., Lieut.-Colonel W. MacGeorge, and William Reid, Esq., were elected Members of the Royal Institution; the Duke of Chartres, the Count of Paris, Stephen Goodfellow, Esq., M.A., and Alexander Mackintosh, Esq., were admitted Members of the Royal Institution. The following Professors were re-elected:—William Thomas Brande, Esq., D.C.L., F.R.S., Hon. Professor of Chemistry, John Tyndall, Esq., F.R.S., as Professor of Natural Philosophy. The presents received since the last meeting were laid on the table, and the thanks of the Members returned for the same.

To Unite Stone and Glass.—M. Bru, Curator of the Museum at Narbonne, has discovered that silicate of potash possesses, in the highest degree, the property of uniting surfaces of stone, glass, and pottery. It is applied with a brush to the surfaces which it is desired to bring into contact, and in a few days acquires a great solidity. It appears that the same material can also be successfully used in joinery, and for all the purposes to which common glue is applied. This discovery, which promises to be of considerable importance, was announced by M. Bru to M. Figuier, the Editor of *L'Année Scientifique et Industrielle*, the volume of which work for the present year contains, at p. 481, a paper on the subject, and a letter from M. Bru to the editor.—*Builder*.

Treating Iron in Japan.—A literary friend sends me the following:—"I have just stumbled on the following in 'Mandelslo's Travels in the Indies,' at p. 190, 'They (the Japanese) have, amongst others, a particular invention for the melting of iron without the using of any fire, casting it into a tun, done about on the inside with about half a foot of earth, where they kept it hot with continual blowing, and take it out by ladels full to give it what form they please, much better and more artificially than the inhabitants of Liège are able to do.'" This would really seem to describe, in an imperfect manner, the fact that Bessemer's discovery has been old knowledge for ages in the "far Cathay," and that, like printing and gunpowder, the knowledge of them has only been communicated to, or re-discovered by, his younger brother Japhet. When a boy I myself recollect well a country blacksmith, in the North of Ireland, who used char peat as fuel, showing me, as a curious experiment, that, by taking a tolerably large flat bar of iron from the fire, when at that temperature above the welding heat when its angles liquefy and begin to scintillate and burn off, and then at once blowing upon the bar strongly with a pair of hand or house bellows, the whole mass, for a few seconds, burnt and flew about like a firework, doing so until the stream of air cooled it down too low. I had little notion what fruitful truths lay hid in that little exhibition. These notices of the "heatings in the dark," as Bacon calls such heraldings of every great discovery, may be of interest thus to record for some future historian of iron metallurgy, by whom Bessemer's name will be undoubtedly honoured.—*Robert Mallet*.

Hermised India-rubber.—India-rubber has been known about a hundred years, and only within the last twenty years has it been found of much practical use. In the town of Beverly, Mass., for some years past, there was a manufacturing company than used a devulcanizing process, taking old rubber and making it up chiefly into india-rubber cloth, under a patent with which Goodyear's did not interfere. And for the last four years they have been working the raw rubber by a process of vulcanization without the use of heat. The rubber is put into a solution of chloride of sulphur and sulphuret of carbon, and the change is effected in its properties in a few minutes. This process is called "hermising," to distinguish it from vulcanizing. The patent is Mr. Parmalee's. The hermised rubber possesses substantially the same properties as the vulcanized. It has the advantage, however, of being made of a lighter colour, and therefore of receiving quite brilliant tints. The lighter colour arises from the fact of rubber being less exposed to the atmosphere during the process, which exposure in the ordinary process turns the product almost black; and to make it lighter, zinc white or some other kind of white material is required to be added. India-rubber springs are passing out of use; it being found that the jolting of the vehicle causes the india-rubber at last to lose its elasticity. Vulcanized rubber subjected to the action of steam for the space of about three hours becomes perfectly brittle.

The New Zealand Iron Sand.—The following correspondence on this subject has taken place in the columns of the *Engineer*:—Mr. Mushet writes: "Sir,—Having received from Captain Morshead, for the purpose of converting into steel, about three tons of the Taranaki metalliferous sand, nothing surprised me more than the almost perfect purity of this sand; of which 98·25 per cent was strongly attracted by the magnet, and 1·75 per cent. only of quartz sand remained unacted upon. The analysis of this ore by Messrs. Johnson and Matthey showed the ore to be composed of:—

Oxide of iron	88·45
Titanic acid	11·43
Loss	·12

100·00

Recently I have received from a party not interested in the matter, a fair sample of the Taranaki titanium sand, and which I find is composed as under:—

Magnetic iserine sand	33·60
Non-magnetic ilmenite sand	61·27
Sea sand	5·13

100·00

And according to the analyses given of magnetic iserine and non-magnetic ilmenite, the Taranaki sand as it lies on the shore is composed as under:—

Oxides of iron	61·14
Titanic oxide	29·73
Sand	5·13

100·00

And the yield from the ore in metallic iron will only amount to about 49 per cent. From another source, much nearer home, I have been supplied with a similar titaniferous sand of precisely similar quality; so that I infer that Captain Morshead has been misled as to the purity and richness in iron of the Taranaki sand, which, as supplied to me, appears to have been separated by a magnet from the non-magnetic bulk of the deposit. Or are there two deposits of titaniferous sand at Taranaki, one pure and the other impure? Perhaps Captain Morshead will be kind enough to explain. It will make a most essential difference in the success of the smelting operations which may be undertaken, whether the ore employed be the pure magnetic iserine or the mixed ore consisting chiefly of non-magnetic ilmenite." In reply to this, Captain Morshead writes as follows:—"Sir,—I can have no hesitation in affording to Mr. Mushet, through your columns, the explanation he seeks in his letter of the 20th March, and published by you on March 22. The sand I forwarded to him was, if anything, below a fair average sample, as could be vouched, if necessary, by four or five 'parties,' to use the words of Mr. Mushet, 'not interested in the matter.' There are not two deposits at Taranaki, one pure and the other impure, as suggested by Mr. Mushet. The whole is pure. I did not separate the three tons I gave Mr. Mushet (which were a portion of about ten tons sent over to me) from any other sand by a magnet. The suggestion of picking up such a quantity by such a process is a simple absurdity. If anyone will take the trouble to compare Mr. Mushet's present letter with those formerly written by him on the same subject, he will readily discover that Mr. Mushet, having failed to attain some end proposed by himself at the beginning of our acquaintance, is now seeking to destroy the effects of his former letters, and injure a project he can no longer control. For the present, I am content to rest upon the analysis of the material made (not for me, or at my request) by Messrs. Johnson and Matthey, corroborated as it is by the certificate contained in Mr. Mushet's last letter, of 'the almost perfect purity of the sand,' from which, I am glad to inform him, that a steel,

far surpassing any made by him, has been manufactured by other parties, and which will shortly be introduced, in large quantities, into the market."

Vapour from Water.—Take a glass bottle of very clear glass and well cleaned with sulphuric acid, and afterwards with clean warm water, then place the bottle on a stand or block of wood, and let the rays of a strong light through a lens fall in the bottle, so that the focus of the lens is about in the middle or near the side of the bottle where you want to observe the vapours; when this is done pour a little hot water in the bottle and close it with a loose stopper, then the vapours can be seen very distinctly with a common magnifying glass or microscope with a long focus placed in an angle of about 150 deg. to 170 deg. with the rays of the light. Should condensation take place on the sides of the bottle a little shaking will take it away. If the experiment is made in a warm room, and the bottle well cleaned, as before described, condensation will not be any annoyance. Then raise the bottle so that the rays of the light fall over the surface of the water, and, by careful watching, the vapours can be seen rising from the surface of the water, and also disappearing on the surface of the water. I have seen them to rise from the water, and falling back again, and floating a short time on the surface, then disappear, as a drop of water will do sometimes. Here the vapours are in a restless state, but if the water is poured out of the bottle and placed on the stand again then the vapours will come more to rest. I believe that any person, after observing this, will come to the conclusion that they are water, therefore they cannot be formed in the body of water. If all vapours have disappeared by lowering the temperature above the surface of water a great quantity of vapours are produced in the bottle (miniature fog). This can be done by blowing cold air, or introducing a cold body or a few drops of cold water.—*F. Hoffmann, in the Engineer.*

ANSWERS TO CORRESPONDENTS.

* * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

* * All Editorial Communications are to be addressed to Mr. CHOCKER, and Advertisements and Business Communications to the PUBLISHERS, GRIFFIN, BORN & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

Vol. II. of the *CHEMICAL NEWS*, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1861, and will be complete in 26 numbers.

Metallic.—We do not know where it is to be procured. An advertisement in our columns would at once bring you the desired information.

Arseniuiretted Hydrogen.—*J. O.*—You can prepare this gas by forming an alloy of 32·1 parts by weight of zinc and 37·6 parts metallic arsenic; upon acting on this with hydrochloric acid, pure arseniuiretted hydrogen is evolved, and may be collected over water. The most scrupulous care must be taken that not the smallest quantity be inhaled as it is a deadly poison.

Pink Manganese Salts.—*Enquirer.*—The pink colour of the salts of manganese is generally due to the presence of a higher oxide; sometimes, however, a trace of cobalt is present which causes the colour. The addition of a bitter sulphurous acid at once destroys the colour, if due to a higher oxide of manganese, whilst it is without action on the colour produced by cobalt solution.

Chrome-Green.—*W. D.*—An account of this colour was given in the First Volume of the *CHEMICAL NEWS*, p. 94.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Colour-tests for Strychnia and the Diagnosis of the Alkaloids, by WILLIAM A. GUY, M.B. Cantab., Fellow of the College, and Professor of Forensic Medicine, King's College, London.

THE observations which I am about to make on the colour-tests for strychnia formed part of the three Croonian Lectures on Tabular Analysis, given at the College of Physicians at the end of February and beginning of March of this year. In those Lectures, one form of tabular analysis was illustrated by a table of the alkaloids, and as the construction of the table grew out of a series of experiments on strychnia, and especially on the colour-tests for that important poison, it was necessary to enter into some details respecting those tests. The questions which I proposed to myself for solution were the following:—

1. The best form and mode of application of the colour-tests.
2. Of the colour-tests, which is to be preferred?
3. Are the colour-tests, or is the selected test open to any serious objection?
4. Is it possible, by means of the colour tests, or by any simple modification of them, to distinguish the alkaloids from each other?

Before I proceed to discuss these questions, I must premise that most of the specimens of strychnia and of the other alkaloids on which I experimented were supplied to me by the Messrs. Morson. The majority of them were presented to me by them as specimens of approved purity; the remainder were procured from them from time to time. For a few specimens I was indebted to my colleague, Professor Bentley. Several of the alkaloids in Mr. Morson's series are crystals of large size and great beauty, and the remainder are evidently of the best quality; of some of the more important alkaloids, such as strychnia, brucia, and aconitina, I have more than one specimen. When the results which I obtained did not happen to agree with the descriptions of approved authorities, I made experiments with other specimens, and endeavoured to ascertain the reason of the discrepancy. I may add, that the results stated in these papers are based upon several hundreds of experiments carefully performed, and the reactions noted down at the time. In order to guard against any possible misapprehension, it may be well to state that the term "colour-tests" is used throughout these communications in the sense of tests producing a series, or succession, of colours; and that it is further restricted to the chemical colour-tests as distinguished from the galvanic colour-test.

¹ Substance of part of the Croonian Lectures for 1861, delivered at the Royal College of Physicians; from the *Pharmaceutical Journal*.

1. Form and Mode of Application of the Colour-tests.—The chemical colour-tests for strychnia consist in the peculiar reactions of the alkaloid with sulphuric acid, plus one or other of the following substances:—The bichromate of potash and the ferricyanide of potassium, and the peroxides of manganese and lead. To these may be added, as less generally recognised, the chromate of potash and chromic acid; and it may be well to state that the chromates of soda and ammonia yield characteristic reactions.

To the four recognised colour-tests (the bichromate of potash, the ferricyanide of potassium, the peroxide of manganese, and the peroxide of lead) I propose to add the permanganate of potash.

In order fully to appreciate the action of these tests, it should be borne in mind:—

1. That sulphuric acid, of the strength and degree of purity commonly met with in the shops, when added to, and mixed with ordinary specimens of strychnia, does not produce in them any change of colour.

2. That the acid does not occasion any change of colour in the peroxide of manganese or the peroxide of lead.

3. That the acid, when mixed with a fragment of the bichromate of potash, produces a yellow solution, which passes gradually to a yellow-brown and clear orange.

4. That the acid, when mixed with a fragment of the ferricyanide of potassium, gives a lemon-yellow solution, becoming tinged with blue after long exposure.

5. That the permanganate of potash, treated in the same way, yields with the acid a light green solution, deepening in tint by degrees; then assuming a pink tint at the margin; then, after longer exposure, becoming brown at the centre and lilac at the circumference; and, finally, after still longer exposure, presenting a rich scarlet at the centre and a brown at the circumference.

Now, as the succession of colours produced when strychnia, sulphuric acid, and either of the five substances just specified are brought into contact, are entirely different from those occasioned by the action of sulphuric acid on the five substances in question, and as, moreover, the strychnia, colours develop themselves very speedily, there is no valid objection to the use of these substances as tests. The yellow tint of the acid solution of the bichromate of potash, the lemon-yellow tint of the acid solution of the ferricyanide of potassium, and the light green tint of the acid solution of the permanganate of potash, offer no impediment to the development of the characteristic strychnia colours, and cannot possibly be confounded with them. The same observation applies equally to the mixture of sulphuric acid with the solutions of these salts. When solutions of the strength of ten grains to the ounce of distilled water are added to equal quantities of strong sulphuric acid, the bichromate of potash yields an orange coloured mixture, the ferricyanide of potassium a lemon-yellow, and the permanganate of potash a red-brown. The tints vary with the quantity of the acid and of the

solutions, and they undergo some change on long exposure; but it may be safely alleged that the colours thus produced do not interfere with the production of the characteristic strychnia colours, and that they cannot possibly be confounded with them. But as for medico-legal purposes, it is well to avoid all objections, however captious, the peroxide of manganese, or the peroxide of lead, may claim to be preferred if, on further examination, they should be found to possess other properties entitling them to a preference.

Having shown that strychnia when treated with sulphuric acid undergoes no change of colour, and that the several tests (the peroxide of lead, the peroxide of manganese, the bichromate of potash, the ferricyanide of potassium, and the permanganate of potash) undergo either no change of colour, or such changes only as do not admit of being confounded with the strychnia colours, I proceed to consider in succession,—1. The best way of applying the colour-tests; 2. The best order in which to use the re-agents; and, 3. The best form in which to apply the colour-developing tests.

1. The colour-tests are best shown on slabs of glass coated with white arsenical enamel by the process technically called "flashing."³ But the lids of porcelain crucibles, or white plates, or fragments of any white ware, will answer the purpose very well. If the enamelled glass is used, the tests should be applied to the glass surface. In using the tests scrupulous cleanliness should be observed, and the sulphuric acid and colour-developing tests, if in solution, are best applied by the drop-bottle, as more delicate, and more secure from any soil than the common glass rod. For mixing the several substances together, a glass spatula is to be preferred to a glass rod.

2. The order in which the sulphuric acid and the colour-developing tests should be applied is easily determined by one or two simple considerations. Good and characteristic results may be obtained by mixing the sulphuric acid with the colour-developing tests, and then adding a crystal of strychnia. When so mixed with small quantities of the peroxides of manganese and lead, the acid solution has a neutral tint, which in no way interferes with the full development of the strychnia colours; and even the acid mixtures of the other colour-developing tests are not open to any fallacy if the alkaloid is brought into contact with them as soon as they are made, and before the colours first produced are deepened or changed by exposure to the air. But the method of procedure which begins with dissolving the alkaloid in the acid and then applying the colour-developing tests is to be preferred, inasmuch as the absence of colour in the acid solution is some advantage in itself, as giving full effect to the strychnia colours, while it has the still greater advantage of distinguishing strychnia from several alkaloids (poisonous and non-poisonous), which yield colours with the acid without the addition of the colour-developing substances.

3. The best form in which to apply the colour tests for strychnia is a subject of considerable practical importance, and it is one upon which there is at present no distinct agreement among chemists. Some authorities prescribe the application of the colour-developing substances in the solid form, some in solution, and some who prefer the state of solution use strong solutions, while others employ weak ones. The balance of authority is certainly in favour of applying the colour-developing

tests in the solid form, and my own experience is favourable to this mode of application. It is also commended by the obvious consideration that solution in water is favourable to a rapid development of the changing colours which constitute the test, such quick change of colour being among the most serious objections to the colour tests. At any rate, it must be admitted to be of the first importance to secure as slow a change of colour as possible, in order to give time for the observation of the colours actually produced.

The superiority of the solid form to the solution is easily shown by a comparative experiment. If we take two minute fragments of bichromate of potash of equal size, place them on a slab of white enamelled glass or porcelain, add to one of the fragments a drop of distilled water, and dissolve it in the water, and leave the other untouched; then place on the slab two equal drops of the same solution of strychnia in sulphuric acid, we shall find that on bringing the fragment of bichromate of potash into contact with the acid solution of strychnia, its colour changes from yellow to blue, and when stirred into the liquid with a glass rod or glass spatula yields a rich blue solution, which retains this colour long enough for easy and complete identification, and then gradually assumes the other tints to be presently described, retaining the final tint for hours or days. While, on the other hand, the solution of the bichromate of potash, when brought into contact with the acid solution of strychnia, yields a blue colour at the point of contact, which colour quickly disappears on mixing the two liquids with each other. When, therefore, we make use of the colour-developing tests in substance, we obtain highly characteristic and lasting colours, but when we use them in solution one evanescent colour only. It is true that if to the mixture of the acid solution of strychnia with the watery solution of bichromate of potash we add a drop or two of strong sulphuric acid we obtain a blue liquid, which undergoes the characteristic changes of colour; but the important fact remains that, other things being equal, solution in water greatly impairs the delicacy of the colour tests. If in this comparative experiment we substitute for the bichromate of potash the other soluble colour-developing substances—the ferricyanide of potassium and the permanganate of potash—we obtain the same results.

The injurious effect of dilution with water upon the colour tests is differently shown in the following comparative experiment:—I placed on a porcelain slab four equal drops of the same solution of strychnia in strong sulphuric acid. To two of the four drops I added a drop of distilled water, and then to all the drops, diluted and undiluted, equal minute fragments of the bichromate of potash. The undiluted drops gave highly characteristic results—the usual succession of rich strychnia colours; while the diluted spots gave no indication of the presence of strychnia, but merely a yellow solution. The same comparative experiment gave the same results with the ferricyanide of potassium, the permanganate of potash, and the peroxides of manganese and lead. The ferricyanide gave a lemon-yellow, and the permanganate of potash a pink, solution; while the peroxides of manganese and lead imparted a neutral tint. In multiplying this class of experiments I have now and then obtained a characteristic reaction, and occasionally an evanescent streak of blue; but these were exceptional cases.

The strength of the solution of strychnia in sulphuric acid used in both these series of experiments was one grain in 200 drops; and as the same pipette was used in

³ I have been in the habit of using this enamelled glass for colour-tests for several years. Oblong slabs of the kind described in the text may be obtained at Powell's Glass Works, Whitefriars.

preparing the solution and in the experiments, each drop contained the two-hundredth of a grain of strychnia.

Now, these experiments, though they cannot be taken to prove that the dilution with water of the acid solution of the alkaloid, or the application of the colour-developing substance in solution, must be fatal to the success of the colour tests, whatever the quantity of the alkaloid or of the acid, they do certainly demonstrate the great advantage attending the use of the colour-developing substances in the solid state. The experiments, it will be observed, are strictly logical and comparative. The distilled water added to the acid solution of the alkaloid, or to the colour-developing substance, was the only element of variation in the two series of experiments.

That the indistinct, or wholly negative, results obtained when distilled water is added are not due to mere dilution, or increase in the quantity of liquid present, is shown by the following experiment:—I placed five equal drops of the same solution of strychnia in sulphuric acid (1-200th grain in the drop) on each of three porcelain slabs. I made no addition to the first drop, but added to the second drop one drop of strong sulphuric acid; to the third, two drops; to the fourth, three drops; and to the fifth, four drops. I then added to each spot on the first slab an equal fragment of bichromate of potash; to each spot on the second slab, an equal fragment of peroxide of manganese; and to each spot on the third slab, an equal fragment of the permanganate of potash. The reactions were perfect and characteristic in each case, the colours differing only in depth of tint, but not in proportion to the degree of dilution. The peroxide of manganese was remarkable for the duration of the colours, and the permanganate of potash for their brilliancy.

Having now, as I believe, shown the superiority of the colour-developing tests in substance to the same tests in solution, and demonstrated the disadvantage of introducing into the colour tests the element of dilution with water, I shall reserve for another communication the question of the effect of the quantity of the colour-developing substances on the success of the colour tests, as well as the answer to the three remaining questions.

(To be continued.)

Further Remarks on the Supposed New Metalloid,
by WILLIAM CROOKES.

ASSUMING that further researches on this subject will confirm the correctness of the opinion which I expressed in a former paper,¹ and that the body there introduced to the notice of chemists will prove to be a new member of the large and increasing family of elementary bodies, I have thought it best to give in the present article a few additional observations which I have since made, and also to propose for it the provisional name of *Thallium*, from the Greek *θαλλός*, or Latin *thallus*, a budding twig, — a word which is frequently employed to express the beautiful green tint of young vegetation; and which I have chosen as the green line which it communicates to the spectrum recalls with peculiar vividness the fresh colour of vegetation at the present time.

I have not succeeded in finding this body in any selenium or tellurium ores which I have examined; but two or three specimens of native sulphur, especially some from Lipari, have yielded it, the latter in such

abundance that if the mineralogical specimen which I examined is a fair sample of what this sulphur is like on the large scale, it could easily be employed as a source of thallium in quantity. I have also found small traces of it in some crude sulphur sublimed from Spanish pyrites, for which I am indebted to the kindness of Mr. Thornthwaite.

The plan which I have found most effectual for separating thallium from the associated bodies is the following:—

Finely powder the ore (selenium deposit or native sulphur, &c.) and mix it with its own weight of dried carbonate of soda and half its weight of nitrate of potash; mix thoroughly, and project in small quantities at a time into a red-hot earthen crucible. When it has all been added, keep at a red heat until it fuses quietly to a liquid, when pour it out on to an iron plate. When cool, powder it and exhaust with boiling water until all the soluble portions are extracted. Filter, and add to the filtrate excess of NH_4O and NH_4S ; boil and filter. The precipitated sulphides are now to be boiled in a solution of one part commercial KCy to eight of water, until no more dissolves. Collect the residue on a filter, and wash well. Dissolve this residue, insoluble in KCy , in hot NO_2Cl ; dilute with water and filter if necessary. Add NH_4O in excess, then $\text{NH}_4\text{O.O}$ and boil. Filter, and add HS . Boil for some time, keeping the solution alkaline with NH_4O and smelling of HS . A dark brown precipitate will be produced, which gradually settles to a heavy black powder. Filter this off, and wash it well.

A portion of this, so minute as to be almost imperceptible to the naked eye, introduced into the blue gas-flame of the spectrum apparatus gives rise to a green line of extraordinary purity and intensity, a piece the size of a small pin's head being most dazzling, and quite equal to the yellow line of sodium in brilliancy. From the purity of this spectral appearance, I am inclined to think that the precipitate is thallium itself, uncombined with other bodies, and reduced by the HS from the state of oxide. This, however, is only conjecture. The quantity of the precipitate which I now have is far too small to settle the point by direct experiment. I am at present endeavouring to find a source of thallium which will yield it in quantity, and if, as I hope to be, successful, I propose giving further particulars at a future time.

PHYSICAL SCIENCE.

Early Researches on the Spectra of Artificial Light.

WE print below a most important paper connected with the above subject. We cannot, of course, give the coloured diagrams with which it was originally illustrated; but we can assure our readers that, after making allowance for the imperfect state of chromolithography sixteen years ago, the diagrams of the spectra given by Professor Miller are *more accurate* in several respects than the coloured spectra figured in recent numbers of the scientific periodicals.

In corroboration of this we need only refer to the drawing of the calcium spectrum as given by Professor Miller. In it is prominently given the dark blue or indigo line, which has not been noticed by Bunsen and Kirchhoff, and the omission of which from their coloured representations gave rise, a few months ago, to the announcement of the existence of a new metal of the

¹ On the Existence of a New Element, probably of the Sulphur Group. By William Crookes. CHEMICAL NEWS, Vol. III, p. 193, and *Philosophical Magazine*, for April, 1861.

calcium group.¹ In the description of the calcium spectrum given below it will likewise be seen that Professor Miller states that there is a bright streak in the indigo.

*Experiments and Observations on some Cases of Lines in the Prismatic Spectrum Produced by the Passage of Light through Coloured Vapours and Gases, and from Certain Coloured Flames, by W. A. MILLER, M.D., F.R.S., Professor of Chemistry in King's College, London.*²

The inquiry into the cause of the dark lines in the solar spectrum is one involved in so much difficulty and obscurity, and the interest which attaches to its solution, in connection with some of the most refined questions relating to the nature of light is so great, that I trust I shall be pardoned for bringing forward some additional facts bearing upon the subject, however little I may have to say in explanation of them. These facts may, however, at a future period, assist us in arriving at some general conclusion.

In examining the prismatic spectrum of light that had been transmitted through the deep red vapours of the nitrous acid (NO₂), Sir D. Brewster made the remarkable discovery, that the absorption of the rays by this medium differs from that of coloured liquids and solids in general, in the production of a multitude of lines crossing the spectrum in the same direction as those observed by Fraunhofer; these lines being broadest, darkest, and most abundant towards the more refrangible extremity of the spectrum. He found them to occur equally, whether solar or artificial light were employed. Shortly after, Professor Miller, of Cambridge, and the late Professor Daniell, of King's College, extended this inquiry to other coloured vapours,—viz., to chlorine, iodine, bromine, euchlorine, and indigo. Between the spectra of iodine and bromine they discovered a very exact parallelism, the coloured image in each case being crossed through a great portion of its extent by numerous equidistant lines, corresponding both in number and position in the two substances.

This remarkable similarity of action upon light, between bodies whose chemical properties are in many respects so closely allied, induced me, as the subject appeared to have been completely laid aside by the philosophers to whom these observations are due, to examine a variety of other coloured compounds. I was in hopes of discovering amongst other bodies, and particularly amongst compounds of similar nature and properties, a correspondence, if not in the colorific position, at least in the general arrangement of the lines (if any were produced), which are rendered visible by a prismatic analysis of the light that has been transmitted through the different coloured media. This hope, however, I have not been able to realise to any considerable extent. But though the results obtained are many of them negative, as the cases in which no lines occur are much more numerous than those in which they are produced, I have met with some facts which I believe are not generally known, and which may, therefore, possess sufficient interest to warrant my submitting them to the consideration of men of science. The mere enumeration of the substances in which I have failed to

discover them may, besides saving others some fruitless labour, be of some value.

My observations may be referred principally to two heads,—those which relate to the effect of coloured gases and vapours upon transmitted light, and those which arise from experiments on the spectra produced by flames of different colours.

Before detailing the mode in which the following experiments were conducted, I will briefly state the principal results which I have obtained from the first series.

1. In no case where colourless gases are employed have I detected any additional lines. Fourteen different substances were employed, varying in density from that of hydrogen, 0.0691, to that of ether, 2.586, and hydriodic acid, 4.388. Of these bodies three were simple, viz., oxygen, hydrogen, and nitrogen, and eleven were compounds, varying greatly in their mode of condensation, as in binoxide of nitrogen, where the elements unite without condensation; protoxide of nitrogen, where three volumes of the gases become two; and ammonia, in which two volumes are condensed into one; in chemical properties they differed not less widely. Five of these gases were acid, the carbonic, hydrosulphuric, hydrochloric, hydriodic, and sulphurous acid. One ammonia is alkaline, one cyanogen is usually considered an organic radical, one a compound of such a radical, as ether; the remaining one, chloride of sulphur, possesses properties referable to none of these heads.

2. The mere presence of colour is no indication of the existence of lines. Vapours which the eye cannot distinguish from each other will be found in one case, as with bromine, to give numerous lines; in another, as the chloride of tungsten, to give none at all.

3. The probable position of the lines cannot be inferred from the colour of the gas. With the green perchloride of manganese the lines are most abundant in the green, whilst with the red vapours of nitrous acid they increase in number and density as we advance towards the blue end of the spectrum.

4. Simple bodies, as well as compounds, may produce lines; and two simple bodies which singly do not produce them may in their compounds occasion them abundantly. Neither oxygen, nitrogen, nor chlorine, when uncombined, occasions lines; but some of the oxides, both of nitrogen and of chlorine, exhibit the phenomena in a most striking manner. There are, however, oxides, both of nitrogen and of chlorine, which do not occasion the appearance of lines.

5. We find, also, that lines may exist in the vapour of simple substances, as in iodine, which disappear in their compounds. This is exemplified in the hydriodic acid, a combination of equal volumes of gaseous iodine and hydrogen, united without condensation.

6. Sometimes the same lines are produced by different degrees of oxidation of the same substances, a remarkable instance of which is furnished in the oxides of chlorine. Here chemical considerations of interest may assist in explaining the cause.

7. The lines are increased in number and density by increasing the depth of the coloured stratum through which the light is transmitted, or by any cause which increases the intensity of the colour, proving that more lines exist than our instruments or eyes are capable of discerning when the vapour is dilute. This is especially exemplified with iodine and bromine.

8. These lines occur both with polarised and non-polarised light. There is little doubt, although I have not yet made the experiment, that the lines thus produced,

¹ Vide CHEMICAL NEWS, Vol. III. pp. 116 and 129.

² Read (June 21, 1845) at the Meeting of the British Association held at Cambridge, and communicated by the Author to the *London, Edinburgh, and Dublin Philosophical Magazine and Journal of Science*, for August, 1845.

as with the ordinary solar lines, indicate an absence of chemical influence, as well as of the luminiferous portion of the ray.

In all the experiments on transmitted light, the luminous source employed was, unless otherwise specified, the diffused light of day. The different spectra represented in Plate II. were obtained by receiving the rays upon a prism of Munich flint glass, mounted upon Fraunhofer's plan and adjusted to an achromatic telescope, placed at 20 feet from a vertical slit in a brass plate, one-fortieth of an inch in width and about 4 inches long. Half of this slit admitted diffused daylight in its ordinary state, the other half of the aperture was covered by the tube or other vessel containing the gas or coloured vapour. The two spectra were thus placed in juxtaposition, and the lines of Fraunhofer could, in most cases, be traced across the vapour spectrum, furnishing exact points of comparison between the two.

By increasing the depth of the coloured stratum, we increase the strength and number of the lines visible; new and fainter lines being rendered discernible by rendering the colour of the gas more intense. A smaller quantity of some bodies is capable of rendering these lines visible than is required to produce the same effect with others; e.g., a quantity of iodine vapour, just sufficient to give a violet tinge to the air in the tube, renders the lines distinctly perceptible, whilst with a tube of bromine, the vapour of which is as full a red as that of nitrous acid, the lines, though visible, are very indistinctly defined. I have, therefore, in experimenting on permanent gases and vapours of liquids volatile at ordinary temperatures, been careful not to decide on the absence of lines unless the light had been transmitted through a body of vapour at least 9 inches deep. It is possible that in one or two instances of substances which require high temperatures for their volatilization, the employment of a stratum of greater depth might have revealed spectral lines, as, with the exception of sulphur, the experiments were, on account of the difficulty of uniformly heating larger vessels, performed in tubes three-fourths of an inch internal diameter. These exceptions, however, if they exist, will, I believe, be very few, as in no case, by using thicker strata, have I found lines, when in such tubes all indications of their existence were wanting. The vessels I have found convenient in operating on the larger quantities of gases are rectangular boxes of colourless plate-glass, usually cemented with marine glue.

In connexion with the effect of varying the depth of the coloured stratum, I may mention, that if we increase the intensity of the colour—e.g., with nitrous acid by the application of heat, the lines throughout the whole spectrum become much darker, and, where they are few in number, more sharply defined; but where they are numerous, they increase to such an extent as altogether to arrest the passage of the light, and the space from F to G, which in Fig. 4 represents several well-marked groups, becomes one continuous band of shadow. On allowing the tube to cool, the lines in this part resume their former distinctness. Analogous phenomena are observed in the case of iodine. This vapour acts principally on the green portions of the spectrum, and if the vapour be at all dense, the orange and yellow spaces appear crossed by the equidistant lines (Plate II. Fig. 2) which characterise this vapour; and they gradually are lost in the green, which seems blotted out by a uniform shadow. As the tube is allowed to cool, and the mass of vapour becomes rarer and its hue fainter and fainter, the

lines are seen by degrees extending into the green, and at length the whole shaded portion is filled with them. They do not disappear in this part until those in the orange and yellow are gone, and until the last tinge of violet in the tube has completely passed away. In most instances, where vapours, and not gases, are the subjects of experiment, it will be found advantageous to exhaust the air and seal the tube by the flame of a blow-pipe. The vapour of indigo and of several other bodies is thus experimented on without difficulty.

I need not advert to the remarkable but now well-ascertained fact, that in the light of the afternoon and evening lines become visible which at other times are not readily detected, and that those of the red and orange portions of the spectrum, in particular, become much more distinctly marked; but a singular appearance accidentally presented itself to me the other day. I was examining the spectrum of the diffused daylight towards the evening when a violent thunder-shower came on. Lines not before visible were distinctly apparent, and a group in the brightest part of the spectrum between D and E, though nearer to the former line, became very evident, increasing in distinctness with the violence of the shower; as the rain passed away they again faded and disappeared. I have had subsequent opportunities on several occasions of confirming the accuracy of this observation.

In Fig. 1, I have represented approximatively some of the principal groups of lines that I have observed in daylight after transmission through different vapours. No pretensions to accuracy are made in these sketches; they are simply intended to convey an idea of the general position and grouping of the lines.

The two first series, those of bromine and iodine, are produced by simple bodies; the remaining ones by compounds containing only two elements, it is true, but the arrangement of the molecules of which, it is all but certain, is far more complicated than such an apparent simplicity might warrant us in expecting.

In Fig. 1 some of the principal solar lines are depicted as fixed points of comparison.

Fig. 2 gives the general appearance of the lines presented by iodine. The specific gravity of this vapour is 8.707; the lines in this case are more distinct in the orange and yellow portions, and in the green becoming so numerous as to obliterate it. These lines are not sharply defined, but shadow off into the lighter spaces very gradually.² In the more refrangible part of the spectrum I did not discern them.

Fig. 3. Bromine shows lines corresponding to those of iodine. They are less distinct, however, and can scarcely be discerned in the orange portions. The violet end of the spectrum is entirely intercepted. Specific gravity 5.390.

Fig. 4. Some of the principal lines in the peroxide of nitrogen, NO_2 , specific gravity 3.183, the gas is of a deep orange. In this gas one vol. of nitrogen and two of oxygen are condensed into one.

Fig. 5 gives some of the groups exhibited by the peroxide of chlorine, Cl_2O_2 ; these are principally confined to the blue and indigo portions, the colour of the gas being a bright orange. No correspondence between the position of the principal groups in these two gases is observable.

It appeared to me of great interest now to ascertain

² I am informed by Professor Miller, that with instruments of high magnifying power and accuracy of definition, these bands are seen distinctly to be composed of very fine lines, increasing in number and strength towards the central or darkest portion of the band.

what influence the successive steps of oxidation of the same body might have upon the spectrum; and two classes of substances presented themselves as well adapted to this inquiry—viz., the oxides of chlorine and of nitrogen.

Thanks to the researches of many eminent chemists, and especially of Millon and Pelouze in the last few years, we are now in possession of means for preparing and insulating these compounds of chlorine in a state of purity. Finding the lines (Fig. 5) in the gas extricated from chlorate of potash on the addition of sulphuric acid, I next prepared some pure chlorous acid from chlorite of lead (PbO, ClO_2). This salt, on the addition of nitric acid, furnished chlorous acid (ClO_2) in a state of purity. In this gas 2 vols. of chlorine and 3 vols. of oxygen are condensed into 3 vols., and it has a specific gravity of 2.646; and on proceeding with prismatic analysis of the transmitted light, the very same series of lines was produced. Chlorous acid, in very small quantity, is capable of tinging a very large bulk of water of a bright yellow colour. As the gas had so marked an effect on the spectrum, I was induced to try this solution, but failed entirely in discovering lines; the liquid arrested the whole of the more refrangible rays entirely, no light passing beyond the mid-space between E and F.

I now prepared some pure *peroxide of chlorine* (Cl_2O_2), freeing it from chlorine and chlorous acid, by which it is always accompanied, by passing the gas through tubes surrounded with a mixture of ice and salt. The peroxide alone condenses at this temperature, and the deep red liquid thus obtained was allowed to fall into a tube and evaporate. The same series of lines were produced. In this gas, which has a specific gravity of 2.325, 1 vol. of chlorine and 2 vols. of oxygen are condensed into the space of 2 vols.

Euchlorine was next tried. The gas was disengaged from a mixture of hydrochloric acid and chlorate of potash, condensing the compound as before by a freezing mixture. To this compound Millon assigns the curious formula of Cl_2O_{13} . Here, too, I found the same series of lines. Millon's theory of the composition of these bodies is, that the peroxide of chlorine is a compound of *chloric and chlorous acids* in single equivalents, as it is immediately resolved into these two acids by the action of alkalis; and he considers the *enchlorine*, or chlorochloric acid, as he proposes to call it, a compound of 1 eq. ClO_2 with 2 ClO , the action of acids, immediately resolving it into those acids in the proportions just mentioned. Certainly the occurrence of similar lines in all three, although the condensation varies, does not militate against this view, but increases its probability.

Millon's new compound, chloro-perchloric acid, which results from the action of solar light on chlorous acid, I have not hitherto obtained in a state of sufficient purity to pronounce upon.

It is remarkable that the *hypochlorous acid* (Cl_2O), though of a bright greenish-yellow, furnishes no such lines. The density of this gas is 5.881, 2 vols. of chlorine and 1 of oxygen being condensed into 1. It is an interesting fact, that the colourless *protoxide of nitrogen*, in which 2 vols. of nitrogen and 1 vol. of oxygen are condensed into 2, having a specific gravity of 1.524, has also no sensible effect upon the spectrum.

In the series of oxides of nitrogen, the *binoxide*, NO_2 , in which 1 vol. of nitrogen is united with 1 vol. of oxygen without condensation, also a colourless gas, has no effect on the spectrum. No oxide corresponding to this in the chlorine series is as yet known.

Hyponitrous acid I have not isolated in sufficient purity to furnish trustworthy results.

Fig. 6 represents the grouping of these lines as seen in daylight transmitted through the vapours of perchloride of manganese, which is readily prepared by adding a few crystals of permanganate of potash to oil of vitriol in a test tube, and dropping in a fragment of fused chloride of sodium, a green vapour (Mn_2Cl_2) is immediately liberated, which is, however, quickly decomposed by the moisture of the air. It will be remarked, that in this vapour, the colour of which is green, the lines are most abundant in the green part of the spectrum, the green tint of the gas being due principally to the mixture of the blue and yellow rays.

The *perfluoride of manganese*, which corresponds in composition to the perchloride, does not yield any lines that I could perceive, but the moment a fragment of common salt is dropped into the mixture from which the fluoride is being disengaged, the lines of the perchloride make their appearance. Both the perchloride and perfluoride are decomposed by water, and on dropping in a little of this fluid into the tube of perchloride, all the lines instantaneously disappear. The purple vapour of the permanganic acid, in which the number of equivalents of oxygen corresponds to that of chlorine and fluorine in these compounds, is equally inactive with the fluoride.

I have examined very many other substances which yield vapours of different colours, but have not succeeded in finding any which give distinct lines besides those above mentioned, with the telescope which I employed. It was not, however, an instrument of very high power.

Simple bodies:—

Chlorine.—Greenish-yellow colour; specific gravity 2.47. This is the more remarkable, as bromine and iodine both give them.

Sulphur.—Yellow; specific gravity 6.654.

Selenium.—Yellow.

Compounds:—

Selenious acid.—Yellow (SeO_2).

Hypochlorous acid.—Yellow; specific gravity 2.993 (Cl_2O).

Oxychloride of chromium.—(CrClO_2); red vapours.

Oxychloride of tungsten.—(WClO_2); red vapours.

Terchloride of tungsten.—(WCl_3); red.

Sesquichloride of iron.—(Fe_2Cl_3); reddish brown.

Perfluoride of manganese (Mn_2F_4).—Greenish yellow. This is remarkable, as the perchloride gives a very distinct series.

Permanganic acid (Mn_2O_7).—Purple. This is beautifully shown by allowing a drop of water to fall into a tube full of the perchloride of manganese, when all the lines immediately disappear.

Indigo.—Splendid crimson vapour ($\text{C}_{16}\text{H}_5\text{NO}_2$).

Alizarine from Madder.—Orange vapour ($\text{C}_{20}\text{H}_{12}\text{O}_{10}$). Both these substances require careful management in the sublimation, as they are readily charred, and a small portion is always decomposed, whatever the amount of care employed.

In making experiments on coloured flames, I generally used an alcoholic solution of the compound on which I was experimenting. A common cotton wick, supported in a small glass tube, furnished the lamp whose flame I wished to examine. This little lamp was placed opposite the fissure, in a tin box, the side of which next the slit

* Professor Miller informs me, that by means of an instrument of superior quality, he has succeeded in satisfying himself that lines are produced by this vapour.

was permanently open, whilst the opposite side was furnished with a door, opening outwards and upwards so that by a string it could be raised to admit the light of day, and would afterwards close by its own weight when allowed to fall back. Fraunhofer's lines (Plate III., Fig. 7) thus again served as points of comparison; the comparison, though not rigidly accurate, being still very nearly so, and perfectly sufficient for my purpose.

Fig. 8 in Plate III. exhibits the remarkable spectrum given by a solution of *chloride of copper*. Several intervals of absolute darkness here occur, interrupted by bright lines of great intensity, particularly in the green and blue spaces. The general hue of the diffused light is a bluish-green.

Fig. 9 represents the spectrum from the green light of *boracic acid*, in which, besides the bright streak at D, five well-marked bright bands occur in the yellow and green, and a narrow line in the indigo.

Fig. 10 is the spectrum from *nitrate of strontia*, the red and orange portions of which are particularly developed, and are crossed by three very strong black lines; a bright line will be remarked in the blue, and another in the indigo.

Fig. 11 is that from an alcoholic solution of *chloride of calcium*; besides the lines in the orange, there is a very brilliant yellow streak at D, and two bright bands in the yellow; in addition to these is a bright streak in the indigo.

Fig. 12 represents the spectrum of a flame coloured by *chloride of barium*. It is in its features intermediate between that of strontia and lime; the most remarkable character is in a bright streak in the orange, another in the yellow, and one in the indigo.

Even *chloride of sodium*, though the intensity of the light is accumulated in a bright band near D, shows a marked tendency to the occurrence of bands in other parts; a distinct, though faint light extending far into the indigo, when a bright streak terminates it almost suddenly.

Chloride of manganese gives indications of the occurrence of bands, though but feebly. I have also tried solutions of the chlorides of iron, zinc, cobalt, nickel, mercury, and magnesia; in all a feeble band occurs in the green portion, as represented in the three last spectra; this is probably connected with the disengagement of chlorine from the salts during combustion; and the bichloride of mercury gives a bright streak near G in the indigo.

The combustion of phosphorus in the open air gives a pure spectrum without lines. I tried it also in chlorine, but did not obtain any very clear spectrum, as the deposition of chloride on the jar quickly rendered it opaque.

Another source of light was furnished by the ignition of different substances in the oxyhydrogen jet: the light thrown directly upon the prism was too intense for the eye to bear, I therefore received it on a sheet of white paper, and employed the diffused light so obtained. In the spectrum from charcoal nearly midway between D and E, a very short brilliant streak was visible, and the same streak appeared when the flame was thrown upon a fragment of dried *alum*.

Lime and strontia give results similar to those furnished by the solution of their salts when used to tinge the flame of alcohol, but not quite so well marked. *Baryta* melted too rapidly to furnish any satisfactory result.

Zinc, iron, steel, and platinum gave brilliant spectra, but no lines except that at D were visible. *Copper*,

lead, and antimony melted without giving light sufficient to make any satisfactory observation.

It may be interesting to remark, in connection with the speculations on the absorptive action of the sun's atmosphere, that if solar light be transmitted through a flame exhibiting well-marked black lines, these lines re-appear in the compound spectrum, provided the light of day be not too intense compared with that of the coloured flame; this may be seen in the red light of the nitrate of strontia, and less perfectly in the green of the chloride of copper. *It would, therefore, appear that luminous atmospheres exist in which not only certain rays are wanting, but which exercise a positive absorptive influence upon other lights.*⁵

It was my intention to have instituted a comparative series of experiments with the light obtained by ignition of the metals by the voltaic battery, but this point has already, I find, engaged the attention of my friend and colleague, Professor Wheatstone; and he has made it the subject of an investigation, characterized by his usual ingenuity and accuracy.

PROCEEDINGS OF SOCIETIES.

SOCIETY OF ARTS.

Wednesday, April 10, 1861.

Lord A. CHURCHILL, M.P., in the Chair.

At this Meeting Dr. JOSEPH MILLIGAN read his Paper on "*Tasmania: its Character, Products, and Resources*," many points of which are worthy of more than a cursory notice. We need not go into the historical and geographical portions of the Paper, as most of our readers are probably aware that Tasmania, *alias* Van Diemen's Land, was first discovered on December 18, 1642, by Abel Jansen Tasman, and was occupied as a British settlement in the autumn of 1803. Nor does the convict question come exactly within our province so we pass it over, and will quote Dr. Milligan's own words on the matters of the Trade and Population of the Colony.

"As the prosperity, wealth, and importance of a new country may be said to depend entirely upon population operating on its natural resources and capabilities, I shall briefly state its progress in Tasmania.

"In the year 1810 the number of inhabitants was	1321
" 1820 "	5400
" 1830 "	No return.
" 1840 "	46,057
" 1851 "	69,187
On Dec. 31. 1859 "	86,451

"And allowing the recent rate of increment down to the present year (1861) the number would be now nearly 90,000.

"So general was the exodus of the working population during the gold digging period of excitement, that the emigration from Tasmania in 1851-2 and '3 amounted together to 35,077; and it is shown by statistical returns that upon these three years there is a balance against the colony of emigration over immigration of more than 10,000 adult individuals, who were poorly replaced by the arrival of families amongst whom were 6000 women and children. An abstraction of so large a proportion from the adult labouring classes in the colony inflicted a considerable check, and told for some time very distinctly on the results of its productive industry. For instance, the breadth of

⁵ This paragraph (the italics of which are our own) shows that Professor Miller has anticipated, by nearly sixteen years, the remarkable discovery, ascribed to Kirchhoff, of the opacity of certain coloured flames to light of their own colour.—ED. C. N.

land in wheat crop in 1851 was 66,236 acres whereas in 1853 it amounted only to 44,123, and in 1854 to 42,920 acres; a state of depression from which it had so far recovered in 1859 as to have attained in that year to 60,314 acres.

"Wool, which in the early times of the colony was permitted, it is said, to rot in heaps on the premises of the settlers, and which from its coarse and low character at the time scarcely deserved a better fate, has been so highly improved in later times, and increased in quantity so immensely, as to have long occupied the place of the principal export and mainstay of the colony. This important end has been attained through repeated and long-continued crosses with the sheep (both ewes and rams), selected from the finest merinos and Saxon flocks in Europe by enterprising colonists, and by the agents of the Van Diemen's Land Company, the purity and excellence of whose live stock of every description long maintained a high character, and fetched the highest prices. The capabilities and suitability of Tasmania for the production of wool of the finest fibre and highest value for the purposes of the manufacturer is well known. The high prices commanded in the English market by wool from the flocks of Messrs. Kermod, Smith, Macleanachan, &c., practically attest the fact. Its character was acknowledged to be of the highest order at the London Exhibition of 1851, and at Paris in 1855. The capacity of the island for maintaining a much larger number of sheep than are at present depastured there can scarcely be doubted. For a long time sheep-owners in Tasmania cultivated fineness and softness of fibre exclusively, and the result was a delicate animal and comparatively light carcase, but a change took place with the rise in the value of animal food, and for many years past it has been the aim of flock-owners to combine length of staple with fineness of fibre to the utmost extent which they can command, a course by which they obtain a much heavier fleece, and a larger and probably hardier animal. With this view the highly improved merinos have been crossed with the Leicester, New Leicester, and South Down breeds, &c., and in many instances with great success. From the statistical tables published by Governments are extracted the following return of sheep depastured in the colony, and of the value of wool exported therefrom in the years mentioned. In 1823 wool was exported to the extent of about 1000 bales. In the year

	No. of sheep.	Value of wool.
1839	898,590	£194,647
1844	1,145,089	176,269
1849	1,712,291	202,334
1854	1,831,308	325,384
1859	1,697,199	467,968

There appears to have been a falling off in the number of sheep in the colony since 1854, but on closely examining the returns I find the weight of wool exported in 1854 stated to have been 4,419,276 lbs., while in 1859 it was 6,107,903, and as there is a nearly corresponding difference in the value, it may be concluded that small sheep of short wool and light fleece, had been replaced to some extent with sheep of larger frame and longer and heavier wool. Upon artificial pastures, along the north and north-west coast, where the climate is humid as well as warm, the Leicesters attain a size and weight little short of the prize animals exhibited at cattle shows in England, but they are not calculated to thrive on the comparatively thin natural pasturage. The Cheviots have been introduced, and as might have been expected, are found to thrive prodigiously and to increase rapidly, but it is a questionable proceeding which would replace the merino crossed with Leicester blood, yielding a fleece of fine wool of rather long staple, for a breed which, however hardy, is remarkable for the vulgarity of quality in the wool throughout its fleece, and which scarcely bears a fleece heavier than that of the animal it supersedes.

"The amount of increase realised from breeding flocks in Tasmania is dependent to a great extent upon the condition (as to flesh) and health of the ewes, upon the nature of the pastures as to the abundance of grass, or the reverse, and upon the nature of the weather at that critical season. On good, well sheltered pastures, with ewes in fair condition, I have often seen upwards of 100 per cent. saved; if at any time the yield falls much below 80 per cent. there is ground for suspecting some mismanagement; if it falls below 40 per cent. gross defects of management must have existed. One of the most ordinary causes of failure of increase in sheep husbandry is the very prevalent custom of over working the grazing, so as to produce an unnatural delicacy of constitution in the stock.

"Sheep farming, from the earliest times of the Australian settlements as the resort of free colonists, has been regarded as the most profitable mode of investing capital. In flocks where there is a fair proportion of breeding ewes of wethers, and other dry sheep, the clip of wool is considered to be more than sufficient to defray all charges of management and the value of the annual increase becomes the net measure of profit accruing. There have occurred some singular vicissitudes in the value of sheep in the Australian colonies. In 1809, prices were very high, in consequence of a large exportation for two or three years to the new colony of Port Philip, but in 1843 sheep were selling at 2s. 6d. per head in that settlement, and at the same time fetching very low prices in Tasmania. The boiling-down process was discovered, and immediately prices assumed a comparatively high figure, and small capitalists who had purchased extensively at the previous extremely low rates, found themselves suddenly converted into men of large fortune. Many Tasmanian settlers became at that period large proprietors of sheep in Victoria, and were proportionately enriched."

Next, as to whale-oil, the Lecturer said:—

"The first notice which I have met with of export of oil from the colony is an entry of 726 tons in 1822. The following quotations will give an idea of the average annual yield of the Tasmanian whale fisheries:—

	Vessels.	Tonnage.	Value of Oil and Whalebones.
1839	26	3146	£119,113
1849	34	7791	37,824
1859	No return.		63,325

"From which last entry it would seem that this branch of trade, has entirely recovered from the blow it received through the loss of crews at the time of the gold diggings."

On the subject of corn we find the following:—

"Wheat has been named as one of the staple products of the colony. In no part of the world is it raised with greater facility or of more excellent quality. There is now exhibited at the Crystal Palace, Sydenham, a sample grown by Mr. Axford, of Bothwell, Tasmania, which weighed 70lbs. per imperial bushel. Samples sent to the London Exhibition of 1851, and to Paris in 1855, were pronounced to be of first-rate quality, and obtained medals. At Circular Head, and in other districts in the island, 50 bushels to the acre have been reaped. The average return, notwithstanding, is comparatively small, as it is not believed to exceed 20 bushels to the acre. The agriculturist possesses, however, in the equability of the seasons and in their genial character,—in the mildness of winter weather and the length of the winter day—and in the certainty of favourable weather during seed-time and harvest, more than equivalent. Besides, there are the best reasons for believing that much of the wheat produced in the colony is grown on land which, from having borne one crop of wheat after another for a long series of years, has become partially exhausted, and that 20 bushels per acre would be very far below the average return under a skilful rotation and proper system of manuring. At present

it is the boast of the Tasmanian farmer that ordinarily he applies no manure to his land. A few select farms, in various parts of the colony, such as 'Clarendon,' the estate of Mr. J. Walker, on the Derwent River, and some few suburban farms, such as that managed by Mr. Shoobridge, in the close vicinity of Hobart Town, form marked exceptions to this slovenly and wasteful want of system, and make, both in cereals and root-crops, the largest and heaviest returns for the liberal and judicious course of husbandry to which they are subjected. It is therefore a reflection on the farmers of Tasmania, rather than a disparagement to its soil or climate, to say that the return of wheat to the agriculturist is generally so much less than it ought to be. There is still another mode of explaining the occurrence of light crops. The best lands are usually the most heavily-timbered, and it has not at all times been convenient to the settler to select for cultivation the land best adapted to this object in preference to that which is naturally clear of trees, or nearly so. Hence it happens that there have been brought under corn tillage much land altogether unfit for the growth of wheat, without heavy aliment in the shape of manures, which it rarely or never obtains. The great advantages which the Tasmanian farmer enjoys in the fine weather of winter for out-door labours—of spring for his seed time, and of autumn for his harvest, as it relieves him of all anxiety, may well reconcile him to a comparatively light return, but it is not right that a deficiency arising out of defective farming should be attributed to the soil; let the onus rest on the right shoulders. The price of wheat is now, and has been for some years, dependent less upon the domestic relation between the quantity produced and the number of mouths to be fed, than upon the demand which the market at Melbourne may present. Indeed the Melbourne markets, it may be said, do now at all terms most naturally modify, if not absolutely rule, the prices of provisions in the neighbouring colonies. At the same time it is matter for congratulation to Tasmania, and her wheat-producing rival, South Australia, that this Babel of the South does afford them a market for every variety of agricultural produce which they can raise. Wheat has been sent from Tasmania to the London market on more occasions than one, when very low in price within the colony, and at a period antecedent to the existence of a gold colony in its neighbourhood, but although the quality of the grain was highly appreciated, never with a result to encourage the belief that such speculations might expand into the dimensions of a regular trade. The freight and charges consequent on a long voyage, and on exposure to many casualties, have invariably absorbed the whole margin left for profits. The colonial market may therefore be said to be the only outlet at present for Tasmanian wheat; but it is a market already making large demands, and widening from day to day with every addition to the digging population, and with every fresh advance colonisation makes in the direction of those regions in Australia where tropical heats forbid the attempt to cultivate the cereals of temperate climates."

After a slight digression, Dr. Milligan returned to wheat and allied cereals, telling us that

"The amount of wheat exported from the colony,—

"In 1849, was 296,236 bushels, valued at \$51,722:

"1859, " 196,405 " " £92,861.

The flour exported in 1859 was valued at £105,128. The *Price Current* of the 23rd of January last, just received from the Colony, quotes the price of prime samples of wheat at 7s. to 7s. 3d. the bushel. The cultivation of wheat admits, it may be added, of almost boundless extension in Tasmania, every probability being in favour of the opinion that the yet uncultivated portion of the Colony contains lands of the richest character, and that as these are brought under tillage a very much higher

average yield of wheat will be obtained, altogether independently of increment from improved modes of culture.

"The usual return from ordinary soils, and in situations adapted to the growths of this grain, may be taken at about 35 bushels to the acre. There is a sample of Tasmanian oats, exhibited at the Crystal Palace, Sydenham, which weighed 49 lbs. per bushel—the yield having been 60 bushels to the acre. The value of oats exported in 1859 was £94,968. In the *Price Current* of the 23rd of January last, from Hobart Town, the price quoted is 3s. per bushel. Barley is not a favourite crop with farmers in Tasmania. The variety known as Cape barley is grown pretty generally in the autumn and winter, in order to be cut very early in the season as green-feed for cattle, and the yield is usually rather heavy. The export of barley is trifling. Of other agricultural products, the most important is the potato. This crop is chiefly cultivated along the estuaries of the rivers opening into Bass's Straits, and at Circular Head, Table Cape, and Emu Bay, on the north side of the island, and along the shores of D'Entrecasteaux Channel, the Huon River, Brown's River, and the Derwent River—near Hobart Town—on the southern side. The potato of Tasmania is far superior to that of any part of Australia or New Zealand; it is quite equal in point of dryness to the best potato grown in England, and very much to be preferred in flavour. The ordinary return obtained in its cultivation varies excessively; the diversity is due as much probably to varieties of tillage and treatment as to difference in the constitution of soils. A mean of the produce of the whole Colony produces five tons to the acre; the best farmers do not expect more than seven or eight tons, but the yield in some cases is more than ten tons to the acre. In the Statistical Table for 1859, it is stated that 7777 acres of land, cropped with potatoes, yielded 41,493 tons:—

In 1849 the price of potatoes in the colony was £6 per ton.

"1854 " " £25 to £30 "

"1859 potatoes were sold at " £3 and £4 "

In December, 1860, the last shipment from Hobart Town,

360 tons, sold at " £8 8s.

Potatoes were exported in 1857 to the value of £61,408.

" " 1859 " £42,906.

"The turnip crop is quite as hazardous in Tasmania as in England, but of far less critical importance to the farmer, live-stock being by no means so dependent on housing and artificial food there as they are in England during the winter season. Mangold-wurtzel and carrots are both well suited to many Tasmanian soils, but are not much grown.

"HAY.—English grasses are cultivated rather extensively for hay, and yield a fair return. As provender for horses it is always in demand for domestic consumption, and for the Melbourne market. The price in Hobart Town in December, 1860, was £4 and £6 per ton.

"Butter and cheese were exported in the year 1859 to the value of £13,877. The dairy is rising in estimation among farmers as a source of profit; and the butter and cheese of Tasmania has acquired a high character in the neighbouring colonies. The last quotations at Hobart Town (23rd January) give for fresh butter 1s. 3d. to 1s. 6d., and for cheese 1s. 6d. to 1s. 9d.

"LIVE STOCK.—Horses, sheep, cattle, and pigs were exported from Tasmania to the value of £60,900 in 1859.

"The feats of Tasmanian horses on the turf early established for the colony the reputation of possessing the best blood and bone in the Southern Hemisphere. The late Governor, Sir W. Denison, was a warm patron of the turf, and frequently went out with the hounds, proving himself as fearless as firm in the saddle. The gold of Victoria has now effected a transfer of much of the horseflesh of Tasmania to the opposite shores.

"The breeds of cattle which have been introduced into

the colony are the Durham or short-horn, the Hereford, the Ayrshire, the West Highland, and the Devon. These have all, at one time or other, and to a greater or less extent, been crossed with an original coarse long-horned variety, betraying Indian lineage or connection, and derived probably from New South Wales, in the very earliest times of the colony. The Durham is the favourite breed, but it carries a frame and carcass too large for the natural pastures, save in exceptional localities, and it is too delicate in constitution; the Ayrshire maintains in the colony its high reputation as a milk cow; but the Devon is by far the best adapted in frame, constitution, and kindly feeding properties, for the natural pastures of the island, and it is decidedly a comely animal. The kyloe, or West Highland breed, promises to yield a cross extremely well-suited for the wild, warm, and humid feeding grounds to the westward. The number of horned cattle in the island in 1859, appears, by Government tables, to have been 79,950. Pigs are extensively cultivated by farmers of every degree. In the early times of the colony a few were allowed to run wild in the bush, where they lived chiefly on fern roots; they have long since been extirpated. The number in the colony, as per statistical return for 1859, was 32,008.

"Fruit has within a few years acquired importance, as an article of export from the colony. Surplus apples used, in bygone times, to be converted into cider, which was given to sheep-shearers, haymakers, and harvestmen, or sold at a moderate rate. They are now sent to the Melbourne market, where the demand for them is increasing.

"There are in the colony more than 100 varieties of apple; many of them are of finer flavour than the original sorts in England, and they attain to a larger size. There are of pears more than 50 varieties, and amongst them are some of the finest quality, and some of the longest keepers. There are 25 sorts of plum, 12 kinds of cherry, 6 apricots, 1 nectarine, 30 varieties of the vine, 6 kinds of the fig-tree, mulberry, medlars, almonds, many sorts of gooseberry, currants, raspberry, &c. Most of these fruit trees bear in great profusion, and the different fruits ripen more perfectly, and are thought to possess higher flavour than the same sorts in England. Peaches and plums are still often allowed to fall, and go to utter waste under the trees in large quantities, and so also with other fruits not unfrequently.

"The value of fruits and preserves exported—

"In the year 1849, amounted to £6976."

1859, " £62,430.

We have not space for the whole of Dr. Milligan's observations upon the timber of Tasmania, but will transcribe a few particulars respecting the well known "blue gum" tree, which attains a height of 350 feet or more, and whose circumference often exceeds 100 feet.

"Planks of this wood were cut for the International Exhibitions at London in 1851, and Paris, 1855, having a width of 20 by 6 inches, which measured respectively 145 and 160 feet in length, a length which might be extended to 200 feet if specially required, as the trunk or bole of this tree often measures 220 feet and upwards to the first limb. There is, however, a practical difficulty in the shipment of such long lengths when ready, as few vessels can be found to stow them on board. The timber of the blue gum has been found nearly, if not quite, equal to oak for shipbuilding. Vessels of 400 to 500 tons burden and under, constructed of it, have from time to time, during many years, been turned out of the ship-yards of Messrs. Degraives, Watson, Ross and Macgregor, &c., at Hobart Town, and it is the proud boast of Tasmanian ship-owners that the age of the colony is not yet such as to have fairly tested the durability of this timber.

"A series of carefully conducted experiments, by Mr. Mitchell, upon scantlings of blue gum, of the same dimensions as those employed by Captain Baker, in his experi-

ment on morung saul, and of Professor Barlow, in his experiments on teak, and other timbers, have established the following comparative results:—

" Specific gravity of Blue Gum . . .	=	1090
" " Morung Saul . . .	=	1054
" " English Oak . . .	=	969
" " Teak . . .	=	745

"Elasticity remaining perfect, the deflection and weights sustained are:—

Blue Gum . . . 2625 inches deflection and weights	776 lbs.
English Oak 1590 " " "	150 "
Morung Saul 1175 " " "	450 "
Teak . . . 1151 " " "	300 "

"The breaking weights of each in pounds were:—Blue Gum, 13,330; Morung Saul, 1192; English Oak, 637; Teak, 938. The value of direct cohesion on a square-inch of timber is:—Blue Gum, 93,408; Ash, 17,337; Teak, 15,550; English Oak, 10,853. These results exhibit a superiority in favour of blue gum so overwhelming as to distance all competition. It only remains to secure for the important practical purposes of ship-building, &c., &c., timber equally well seasoned as the samples operated upon by Mr. Mitchell, to realise in its actual employment and use the full advantage of the high qualities it is found to possess. Were shippers of this timber bound by legal enactment in the colony to prove in each case that the timber has been cut and seasoned in the scantling for five years, it would, probably, be sufficient to protect the trade from the imposition of inferior sample, and the character of the timber from doubts and aspersions as to its superior value. Looking at the paramount superiority of this timber in the qualities most valuable for ship-building purposes, it may fairly be questioned whether full justice is done to its merits by the position (Class A 1, for 9 years) assigned by Lloyd's to ships built of it.

"The enormous demand which has of late years arisen in England and other countries for railway sleepers of wood has suggested to Tasmanian colonists the advisability of proposing the employment of the blue gum of the colony, on account of its hardness, strength, and durability, and they urge that, as sleepers of blue gum can be supplied at 5s. or 5s. 6d. each, which would last more than double the time of the pine sleepers now in use, which cost 3s. 6d., a vast saving of outlay in money and labour, would, by its adoption, be effected to the railway companies, &c. Several shipments of sleepers of the blue gum have recently been forwarded to London, in order to their being put upon their trial. It would be but fair to the future character of the blue gum, that the extent of seasoning to which these sleepers have been subjected previous to shipment should be made known, so that if oversight or negligence has led to the export of green wood, any injury which the reputation of the timber might thus sustain may be obviated, and the recurrence of so objectionable a practice prevented. The blue gum has been used for telegraph poles, and found to answer well. The swamp gum, the stringy bark, the iron bark, &c., will be found scarcely, if at all, inferior in any useful quality to the blue gum when properly seasoned. The blue gum and other varieties of Eucalyptus abound to such an extent along the sea-board of Tasmania as to enable the colonists to say that these timbers can be supplied for an indefinite period of time in any quantity the mechanic world may require.

"There are many varieties of trees in the forests of Tasmania, which yield woods for house-building fittings, implements, &c.; and there are others of great excellence and beauty for furniture, and for purposes of the cabinet-maker. Some fine samples were sent to the London Exhibition of 1851, and to Paris in 1855, and there are now on view, at the Crystal Palace, Sydenham, a few superb specimens of the myrtle-wood *Fagus Cunninghamii*, and the musk-wood, *Eurybia argophylla*—the Black-wood, *Acacia melanoxylon*, and Huon pine, *Dacrydium Frankii*,"

&c. Wherever seen, these ornamental timbers have been much and justly admired for their rich and harmonious tints and beautiful venation, and need only to become more extensively known in order to come into large demand in this market. The source of supply, I may add, is, to all practical intents, inexhaustible.

Building-stones of various kinds,—coal, anthracite, clay, ironstone, red hematite, and galena are all abundant in the island, while gold has been obtained from the detritus of various slate rocks, and serpentine, asbestos, and oxides of manganese have also been found in many places.

However reluctantly, we must now conclude this brief review with a few paragraphs selected from the discussion which followed the reading of the paper.

Mr. JOHN YOUL observed, in the course of his speech, that he had been travelling among the myrtle trees of which the slab upon the table was a specimen, about eighty days previously. They were very beautiful and entire; impenetrable forests extended for distances of fifty miles. The mountain-lakes of Tasmania formed perhaps the most extraordinary natural feature,—many of them were at an elevation of 3000 feet above the level of the sea, and some were of a depth of 75 fathoms.

Mr. EUGENE RIMMEL asked Dr. Milligan for some information concerning various odoriferous plants.

Dr. MILLIGAN said that the *Acacia*, *sassafras* and *musk-wood*, were found in great abundance, but that the *Elizir buccifolia* was not so common.

After various other speeches, a vote of thanks to Dr. Milligan was proposed and passed.

The Secretary has received the following letter since the meeting:—

Products and Resources of Tasmania.

"SIR,—I was unexpectedly prevented from attending the meeting on the 10th inst., or I should have given verbally the few observations upon Dr. Milligan's paper with which I now trouble you.

"It may perhaps appear somewhat ungrateful to ask for further information, after the rather lengthy paper referred to, but Dr. Milligan may possibly be able to add a few points to, and thereby increase the value of, his very instructive communication.

"In the first place, we might reasonably hope for a few more particulars relating to the food-products of Tasmania, both as regards their local preparation and consumption, and also the articles which are now, or may be hereafter, exported for this country.

"Tasmanian wheat I quite believe to be of superior quality, as a general rule, to that consumed in Britain, whether of home or Russian growth; in 1857, a small sample of the grain was placed in my hands, which gave on analysis the following results:—

Water	13.450
Ash	2.210
Potassa	.265
Soda	.390
Magnesia	.233
Lime	.072
Sesquioxide of Iron	.024
Sulphuric Acid	.154
Chlorine	.053
Phosphoric Acid	.945
Silicic Acid	.026
Nitrogenous matter, Gluten, Albumine, &c.	15.750
Nitrogen	2.500
Carbonous matter (and loss)	68.590
Fat or Oil	1.425
Starch, Sugar, &c.	67.165

100.000

"In the preceding figures the proportions of nitrogen, fat, phosphoric acid, and alkalies, will be readily noted, as

being distinctly above the average; I have frequently heard of the superior qualities of the barley of Tasmania, but have never examined samples.

"Perhaps Dr. Milligan could furnish us with some more detailed particulars respecting those food-products of Tasmanian growth, which are, or may be found, specially adapted to meet the requirements of the mother country, and also concerning those plants it would be practicable and advisable to cultivate there for a similar object. It would be interesting to learn what edible roots, if any, could be profitably grown in Tasmania for British consumption; even a non-edible plant yielding large quantities of starch of fair quality, would supply a great and very generally felt want; if I am not mistaken, some rather considerable prizes are (or have been) offered in this country and in Belgium, for the discovery of a means of obtaining starch, suitable for manufacturing and general purposes, from a source not furnishing food for man.

"Although perhaps the cost, delay, and risk, attending transportation, might prohibit the regular importation of many of the food-products of the colony which are of little comparative value, or are consumed in very large quantities, this objection could not apply to those generally somewhat costly substances from which the flavours, the perfumes, and the colouring matters of commerce are extracted.

"I believe experiments have been made with the view of cultivating the vanilla plant, but I am not aware of the result. Then, again, if I am not mistaken, the fragrant *Acacia Farnesia*, and the *Comesperma volubilis*, and several varieties of *Eurybia*, are already grown to a small extent in Tasmania, while it has been stated to me that the same country is favourable for the growth of the *Garcinia Cochinchinensis*, the *Rubia tinctorum*, the *Panax quinquefolium* ("Ginseng") the *Statice tartarica* (perhaps the most powerful tanning agent known) and many other plants of equal or greater importance.

"What is there either to prevent Tasmania from supplying us with large quantities of silk, manna, millet-sugar, and various textile fibres? And, as a final query, perhaps I may ask if any credence should be attached to the rumour—for it seems to be of no very definite character—that truffles of a fine quality have been found in the northern part of the colony.

"Anything that tends to commence or extend the practice of importing to this country the products of any of its colonies or foreign possessions, must be regarded as of no mean importance to the interests of the countries concerned. Three advantages attend the movement: viz. the supplying of home desiderata by British subjects; the more rapid development of the resources of the colony itself; and, lastly, the check that can be had upon the quality of the articles imported,—in other words, upon the practice of adulteration, should it be found to exist.

"I am, &c.

"WENTWORTH L. SCOTT.

"Bayswater, London, W., April 12, 1861."

CHEMICAL SOCIETY.

Thursday, April 12, 1861.

Professor A. W. HOFMANN, F.R.S., President, in the Chair.

Messrs. A. E. Sanson, and H. K. Bamber were elected Fellows.

Professor F. A. ABEL, F.R.S., Director of the Chemical Establishment of the War Department, delivered a discourse upon "The Application of Electricity to the Explosion of Gunpowder." The Lecturer commenced by giving a short historical account of the experiments instituted in this and foreign countries, for the purpose of firing mines and cannon by electric agency, and referred to particular methods of operation adopted by Colonel Verdu, in Spain, and by M. Savare in Paris, and to very extensive opera-

tions carried on by a system organised by M. du Moncel, at the port of Cherbourg, by MM. Dussaud and Rabattu, in 1854. The Austrian system of employing frictional electricity, and results of great magnitude obtained with it, were also briefly referred to.

In reviewing the several methods proposed in our own country for effecting this purpose, the Lecturer described the construction of Statham's fuze, and of the "galvanic fuze," which has for many years been employed in firing guns at proof. The latter consisted of a quill tube, filled with compressed meal powder adapted to a wooden head, in which were arranged two small copper tubes with a fine iron wire connecting them, and surrounded with gunpowder. When, therefore, a galvanic current of sufficient power was made to traverse the thin wire, it became heated to redness and fired the loose powder and the composition in the quill-tube, which being inserted in the "vent" or touch-hole of the gun, ensured the ignition of the whole charge. Among the inconveniences arising from the application of electricity derived from the voltaic battery, were, firstly, the necessity for employing two lengths of wire to complete the circuit, the tedious and difficult operation (in soldiers' hands) of charging the batteries with acid, and the inconvenience and risk of accident attending the transport of the necessary agents.

An extensive series of experiments had been instituted at Woolwich and Chatham, since 1855, by desire of the Secretary of State for War, by Professor Wheatstone and Mr. Abel, for the purpose of ascertaining the relative merits of different forms of electricity applied to the explosion of gunpowder.

The great improvements made in the construction of the induction-coil apparatus by M. Ruhmkorff rendered it desirable that experiments should be instituted, with small battery-power, to obtain the effects of electricity of high tension; and the results were considered so satisfactory, that Mr. Abel pointed to this form of apparatus, as possessing decided advantages for firing a great number of fuzes simultaneously; in all cases, indeed, when the special nature of the operation would warrant the use of a battery. The ignition of six charges of gunpowder in a series was demonstrated at the lecture, by the use of a powerful induction apparatus of Mr. Ladd's construction with small battery-power.

A large magneto-electric apparatus, constructed by Henley, with a lever-armature, was the first instrument tried at Woolwich for dispensing with the use of the voltaic battery. With this a great number of experiments were made in the endeavour to ignite gunpowder and other compositions of a highly inflammable nature. Little success attended these efforts until moistened gunpowder came eventually to be tried. This exploded and led to the introduction of Mr. Abel's first "Magnet-fuze." In describing its general construction, the Lecturer called attention to the invaluable service rendered in these experiments by a particular form of insulated copper wires manufactured according to his instructions by the Gutta-percha Company—two thin wires were separately covered with a non-conducting coating, then laid side by side, and these twin wires further coated and bound up into one by an outer covering of gutta-percha. Whenever a cross section is made in this the two copper wires are severed, and the terminals brought to view. Short lengths of this material were advantageously applied in the fuze-head, and placed so that the moistened powder rested on the bare terminals. Several hundred of these quill fuzes were fired with the large lever-magnet with great certainty, the only failures arising from mechanical defects in their manufacture. As a convenient means of preparing the moist gunpowder in a state fit for priming the fuze, the ordinary fine-grained powder was saturated with a dilute alcoholic solution of chloride of calcium; on exposure to

the air for a day or two the spirit evaporated completely, and at the same time gave the deliquescent salt in the powder an opportunity of absorbing the necessary amount of moisture. The large magnet-apparatus and a supply of suitable fuzes, composed portion of an equipment fitted out during the late Chinese war for the purpose of clearing away the obstructions in the Peiho river.

Since that period an extended series of experiments has led to important improvements in the magnet-fuze. The priming composition is made more sensitive by the employment of a mixture of phosphide and sulphide of copper and chlorate of potash, instead of the moistened gunpowder, and is now so readily ignited that single fuzes may be fired by the smallest magneto-electric machines, such as the American apparatus (a six-inch horse-shoe magnet and rotating armature), recently introduced for medical purposes. The mode of placing the priming material in contact with the poles by the adaptation of a little capsule of sheet tin; the putting together of parts in the general arrangement; and the simple mode of making the necessary metallic connexions were explained, and the fuze in several stages of manufacture exhibited.

Professor Wheatstone, who has been associated with Mr. Abel throughout the course of these experiments, has contrived a very ingenious and portable form of magneto-electric instrument called by him the "magnetic exploder." This will fire a number of fuzes, either simultaneously or in succession, according to the arrangement of wires employed, on merely turning the handle of the instrument, and pressing the stud or key when the requisite velocity of the revolution of the magnet-armatures has been attained, and the preconcerted signal given. [Ten magnet-fuzes, placed in a divided circuit, were then exploded by Mr. Wheatstone's apparatus. The simplicity of the whole arrangement, and its complete control by the operator, became at once apparent.] For the purpose of establishing metallic communication between the magnet-fuzes and the "exploder," one insulated wire is all-sufficient; this need be but of small size, and being led out from the machine, is inserted into one eye of the fuze head; the other requires merely to be connected with the ground by a short length of ordinary copper wire attached to a small metallic plate buried in the earth close at hand. All that remains to be done in order to complete the earth-circuit is to connect the second binding screw of the "exploder" with the ground beneath, using a similar plate or, more conveniently, a short wire passed under and dug in with a spade. In the event of a number of charges requiring to be fired simultaneously (frequently the case in engineering operations), the distant extremity of the main wire is placed in communication with a corresponding number of short branches of insulated wire, each leading to a mine; the juncture of the main wire with the branches is effected by twisting the bare ends together with pliers, binding the joint round with fine copper wire to ensure proper connexion throughout, and then simply covering it with sheet caoutchouc or waterproof canvas, to maintain perfect insulation. The ground wires of the series of mines are, for greater certainty, collected into one, and secured as a single earth connexion. With ordinary attention bestowed upon the repair of any injuries which the insulated wire may accidentally sustain in the course of rough usage, no difficulty is experienced in directing the operations at a great distance from the scene of the explosion. The use of ordinary uncovered wire supported above the ground on poles or stakes, provided with insulators, was referred to as another means of conveying the magnet-current to a distance.

The modifications rendered necessary in the general arrangements for the carrying out of submarine explosions were briefly described. The obstacles in the way of success were represented to be greater in this class of operations (especially when more than one charge has to be fired) on account, firstly, of the increased difficulty in

thoroughly insulating the conducting wire and the necessary connection; and, secondly, because of the flowing in of the water upon the bared poles immediately after one or two in the series were ignited, thus, by completing the circuit, preventing the explosion of the rest. The charge of powder was enclosed either in a tin canister or a mackintosh bag, with a fuse in the midst, and connection established with the insulated wire on the one hand, whilst the other pole was placed in communication with the metal of the canister, or brought out into the water in the case of the vulcanised india-rubber bag.

From a number of experiments made at Woolwich and Chatham, with a small, portable form of hydro-electric machine, fitted up for the purpose by Sir William Armstrong, the possibility of firing many (fifty to one hundred) fuses in series was conclusively established; but, inasmuch as the management of this machine involved some special precautions, and was subject to great loss of power in unfavourable weather, its employment for field purposes was not deemed so advantageous as that of the magneto-electric apparatus which had been introduced to the notice of the Society.

It was stated, in conclusion, that Mr. Abel had found, by very recent experiments, that the latest forms of induction-coil apparatus furnished, with his sensitive fuses, results fully equal in magnitude, and of greater certainty, than those obtained in the field with the hydro-electric or frictional electric machine.

Mr. ALFRED SMEE, after drawing a comparison between the several kinds of electrical apparatus capable of employment in mining operations, stated that there was no instrument which, in his opinion, so completely fulfilled all the conditions requisite for field application, as that which had been selected by Messrs. Abel and Wheatstone. He considered that not only should the magnet be employed for all purely military purposes, but that the system was equally capable of universal application in connection with the blasting of rocks and mining operations generally. Referring to the early instances of the employment of the voltaic battery in the raising of the *Royal George*, and in the removal of large masses of chalk cliff near Dover; he attributed the abandonment of the galvanic system to the inconveniences inherent to the use of the battery.

Dr. W. A. MILLER, referring to the Lecturer's remarks on the Austrian system of employing the plate electrical machine, wished to draw attention to the recently introduced material called "vulcanite" or "ebonite," as one well fitted to take the place of glass in any instruments designed for military purposes.

Mr. ABEL mentioned that the Austrian officers in their report on this subject, allude already to the use of hardened india-rubber (another name for vulcanite), and to the probability of its replacing glass, as being less liable to the condensation of moisture, and not subject to breakage.

Mr. WARREN DE LA RUE pronounced an eulogium upon the perseverance and skill of the experimenters who had brought the magneto-electric apparatus and all the arrangements to such perfection as to accomplish that which would formerly have necessitated the employment of cumbrous machinery, with which it would, however, have been utterly impossible to have produced anything like the perfect results just now exhibited to the Society.

Royal Institution.—The following is the arrangement of Lectures for the ensuing week:—Tuesday, May 21, at 3 o'clock, Mr. John Hullah, "On the History of Modern Music." Thursday, May 23, 3 o'clock, Mr. W. Pengelly, "On the Devonian Age of the World." Friday, May 24, 8 o'clock, Professor J. O. Westwood, "On the Metamorphosis of Insects." Saturday, May 25, 3 o'clock, Professor Max Müller, "On the Science of Language."

CORRESPONDENCE.

Food, and its Adulterations.

To the Editor of the CHEMICAL NEWS.

SIR,—Valonia, as an adulterant of tea, having of late excited some interest, I send herewith a small specimen of the latter, purchased in Westbourne Grove, which contains a notable quantity of the above-named astringent. In the course of the discussion upon my recent paper at the Society of Arts, January 30, 1861—(noticed in these pages)—I believe it was stated that it was impossible, or extremely difficult, to detect valonia in tea; I did not care to reply at the time, not having just then an illustrative example, now, however, I may say that any one who will examine the enclosed "fine Japan tea" by reflected light, under a moderate magnifying power, may easily perceive the peculiar "crystalline aciculæ," characteristic of the presence of valonia.

While on the subject of Adulteration, I may perhaps take the opportunity of slightly modifying a statement of mine in the paper before referred to, concerning mustard which I said was never to be met with pure (in London). This although true at that time, is, I am happy to say, not strictly so at the present moment, for very recently Messrs. Evans, Lewis, and Co., of Diglis, Worcester, have introduced into this metropolis two qualities of mustard which are perfectly pure and genuine, and two others which differ only in containing rather more of the white mustard seed, and husk, and a minute proportion of turmeric, no other substance whatever being present. The samples I have examined were obtained both from Worcester direct, and from various retailers in London. The latter, however,—as I have found in more than one instance—will constantly adulterate this as well as all other mustards, where they sell it loose, and none can be depended upon, except in perfectly secure tins.

I need scarcely apologize for troubling you with these few remarks (which I trust will show my readiness to correct, even a trifling error, as soon as it is pointed out to me)—the importance of pure mustard, either for producing cutaneous vesication, or as a wholesome condiment for the table, being very generally acknowledged.

I am, &c.

WENTWORTH L. SCOTT.

Bayswater, London, W., May 4, 1861.

The Chemical Examination of Waters.

To the Editor of the CHEMICAL NEWS.

SIR,—As a contribution towards the knowledge likely to assist in arranging into chemical compounds the experimental results obtained in the analysis of waters, I beg leave to communicate a few observations in reference to this subject.

Much reliance appears to have been placed on the indications afforded by vegetable colours, as a means of determining the presence of alkaline carbonates among the constituents dissolved in any sample of water under examination; but at the same time that the value of such tests, properly applied, must be admitted, there appears to be a necessity for drawing a distinction between two classes of indications which have hitherto been frequently confounded.

Thus, it is the property of carbonate and bicarbonate of potassa to exercise a direct influence upon the natural colour of turmeric paper, and to change it from yellow to brown. The same alkaline salts have no direct action upon litmus, blue being the natural colour; but if this vegetable infusion be previously reddened by an acid, and red litmus paper be the test employed, the effect of the alkaline carbonate can then only be properly referred to

its power of neutralising this extraneous acid, and in consequence restoring the natural colour of the litmus.

In carrying out some experiments, a short time since, for the purpose of observing critically the reactions afforded by the carbonates of lime, baryta, and magnesia, when dissolved in water impregnated with carbonic acid, the distinctions between the metals of the alkali group and those just now enumerated, appeared very decisive. When carefully prepared turmeric paper was the test employed, it was found that whilst very small proportions of the alkaline carbonates were readily detected, no direct action was apparent with pure solutions of the carbonates of the alkaline earths. When reddened litmus paper was the test used, it was found to be equally affected (restored to blue) by all the carbonates indiscriminately.

With this distinction clearly in view, I have frequently employed turmeric paper as a test for the presence of alkaline carbonates in natural waters. Many samples have not afforded the slightest indication. Artesian well-waters from different parts of London have all furnished direct proof of the existence of an alkaline carbonate among their soluble constituents. The sample of water from the coal strata under Bradford Moor, described by Mr. Abel,¹ possessed in a high degree this alkaline property, evidenced by turmeric, and easily accounted for by its containing no less than 43·5 grains of bicarbonate of soda in the gallon of water.—I am, &c.

JOHN SPILLER.

Woolwich, May 13.

MISCELLANEOUS.

Conversazione at the Society of Arts.—The Members of the Society of Arts held their first Conversazione this Session at the Society's House, Adelphi, on the evening of May 4th. A number of interesting objects were exhibited, including the spectrum apparatus of Bunsen and Kirchhoff, as manufactured by Mr. Ladd, Wenham's binocular microscope, by Messrs. Smith, Beck, and Beck, Messrs. Powell and Eland, and Mr. Baker; Abel's new mine or cannon fuses, some specimens of gutta-percha and varnishes, Indian "talc" (Mica), paintings, &c., &c. The "Exhibition of Recent Inventions" was also thrown open, and in the great room a miscellaneous series of transparent photographs were projected on to a large screen by means of the oxy-hydrogen light, by Mr. C. Jones. The scenes in Egypt and Italy were specially interesting, and the latter included a good portrait of Garibaldi (described as a "party" everyone would recognise) entirely spoilt by the colouring. The evening passed off in a manner which must have proved very satisfactory both to the Council, and to the large assemblage which responded to their invitation.

The Leicester Sewage Works.—With regard to the cost of deodorising the sewer water at Leicester, as the facts connected therewith have been occasionally misapprehended or misrepresented, the following information may not be considered misplaced in a report of this nature. The works erected there by a private company having failed to yield any remuneration, owing to the fact that the great dilution of sewage rendered the proportion of fertilising matter precipitated therefrom too small to be of appreciable value, they were (according to a stipulation in the original agreement) handed over to the Town Council of the borough, who have been in possession of, and have carried them on for above twelve months. It is not generally understood that these works consist of two parts. First, of the pumping engines employed for the purpose of lifting the water at the artificial outfall of the main sewer, which was made considerably lower than the

natural one, which latter was at too high a level to allow of the complete drainage of the lower portions of the borough, and recourse was had to this plan of an artificial outfall, because it was cheaper than the construction of a natural outfall sewer would have been, which (owing to the nature of the locality) it would have been necessary to carry many miles below the borough, in order to reach a level low enough to create a sufficiently rapid current in the main sewers, but this plan was not finally determined upon without a thorough investigation of its merits, and the result has justified its adoption. The second part consists of the deodorising tanks and machinery. The actual cost of the disinfecting process carried on at these works during the twelve months ending November, 1859, was as follows:—The quantity of sewer water deodorised being 1,061,757,200 gallons, or 4,740,000 tons, equal to 2,908,920 gallons per twenty-four hours, or 414 gallons per diem per head of the population. The quantity of slacked chalk lime used was 580 tons, which cost £369 15s. The cost of labour in slacking and mixing the lime amounted to £78. The coals consumed by a small steam engine for working the agitators, and raising the precipitated matter from the bottom of the tanks, amounted to seventy-three tons, and cost £25 11s.; and the cost of labour for working the engine, attending to the tanks and machinery, and for attending to and storing the manure or precipitate was £76 14s., making a total of £550, which is equal to a cost of less than twopence per annum per individual, or twopence for every 16,000 gallons of sewer water deodorised. These works have now been in efficient daily and continuous operation for the last six years, during which period all the sewer water from the borough has been thoroughly disinfected and rendered innoxious before it has been permitted to flow into the river Soar; and to those who can recollect the condition of the Soar at the North Bridge, above and below, in former years, it will perhaps appear a desideratum that was worth paying for to obtain. These works, although commercially a failure, for the reason before given, have been most successful as a sanitary measure, and although the gentlemen who expended large sums in the solution of this important question have been great pecuniary losers, nevertheless, the borough of Leicester has derived great benefit from their operations; and I believe it is an undisputed fact that the sewerage of the borough has been more completely and economically effected than in any other town in England.—*Thos. Wicksteed, C.E.*

ANSWERS TO CORRESPONDENTS.

. In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Magenta Dye.—Cotton without a Mordant writes as follows:—In reading the *CHEMICAL NEWS* for April 27, 1861, I find a letter signed "Sharp, Leeds," saying that Magenta cannot be dyed on cotton without a mordant; but I beg to say that he is labouring under a mistake, as I have for the last three or four months both dyed it in the cotton hank and in the cotton warp, without a mordant, and I can get by far the better colour without, than with any mordant.

Green Extract.—1. There is no proximate principle in yeast which may be separated from it and be used to induce fermentation. Yeast globules are necessary for this purpose. 2. The crystals should be examined—are they organic or inorganic, acid, basic, or neutral?

Ammonia will be answered in a subsequent number.

C.R.—1. We think it is uniformly distributed. 2. It has only been proved in a few instances. 3. In ordinary analysis it would be overlooked. 4. It could only be proved by searching Chemical analysis. Perhaps we could assist you better if you were to communicate privately with us.

A Subscriber.—Papers on the subject are to be met with in the recent volumes of the *Philosophical Magazine*. No connected account is to be met with. Your coil cannot be modified. It may be used as it is, but it will only produce a few of the effects to a very limited extent.

WATER ANALYSIS.

On a recent occasion¹ we had an opportunity of pointing out some notable discrepancies which have arisen from the want of a good general system of classification, according to which the numerical results furnished by the chemical examination of waters might be arranged, and represented in their probable state of combination, or as saline constituents actually present in the water. With the object of eliciting a more decided expression of opinion in regard to this subject, we advert to some additional considerations which seem to necessitate an early and careful review, in order that this frequently-recurring problem, water analysis, may be placed without delay on a more satisfactory foundation.

So little progress appears to have been made in this direction that the remarks of Fresenius, pronounced in the early days of quantitative chemistry, may yet be held as strictly applicable to the present time. This distinguished analyst says:—"With respect to the principles which guide chemists in inferring in what manner the acids and bases are combined as salts in the water, it is assumed that they are united according to their relative degrees of affinity, i.e., the strongest acid is assumed to be combined with the strongest base, &c.—due attention being paid, however, to the greater or less degree of solubility of the salts, since it is well known that this exercises a considerable influence upon the manifestations of the force of affinity. Thus, for instance, when lime, potassa, and sulphuric acid are found in the water after boiling, the sulphuric acid is assumed to exist by preference in combination with the lime. It cannot be denied, however, that this way of proceeding leaves much to the individual views and discretion of the analyst, and consequently that different modes of associating the several ingredients found may lead to different results for one and the same analysis. A general understanding upon this point would be very desirable, because without it the comparison of two mineral waters is beset with difficulties. As long as a general understanding of this kind is wanting, a comparison between mineral waters can only be made with the direct and immediate results of the respective analyses."

The system recommended by Fresenius may be concisely stated as follows:—To boil a measured quantity of the water for a time sufficient to precipitate the whole of the carbonates of lime and magnesia originally dissolved in the water in that form; should carbonate of iron be also present, it will be separated as peroxide in the operation of boiling. The amounts of these constituents severally determined will represent the proportion of lime, &c., in combination with carbonic acid. The lime and magnesia still remaining in solution, and the alkaline bases have then to be estimated. Lastly, the sulphuric acid, chlorine, silica, and other constituents

present in smaller proportion may be determined in the original water. As already stated, the lime not precipitated by boiling should be combined with sulphuric acid; any excess of this acid being placed in union, first with potassa, then with soda; the rest of the sodium to be represented as chloride, and in a similar state of combination also that portion of the magnesium which has not been precipitated on boiling in the form of carbonate. Nitric acid may, however, sometimes aid in retaining the magnesia in a permanently soluble form.

With regard to such samples of water as contain alkali partly in the form of carbonate (readily ascertained by adopting the process referred to by Mr. Spiller, in a letter inserted last week in our columns), the lime and magnesia must in such cases be stated as carbonate; and sulphuric acid, if likewise present, all in the form of alkaline sulphate.

A mere casual reference to the numerous published tables of analyses describing the constitution of mineral waters will be sufficient to convince an unprejudiced mind of the necessity for urging the importance of this subject, and taking steps to obviate the inconvenience arising from the want of an uniform system of tabulating the analytical results.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Expansion of Metals and Alloys, by F. CRACE CALVERT, Ph.D., F.R.S., F.C.S., &c., R. JOHNSON F.C.S., and G. CLIFF LOWE.

HAVING been engaged for some time in investigating several of the properties of pure metals, it was thought desirable to take advantage of having pure metals at our disposal, together with a series of definite alloys of those metals, to determine their rate of expansion; and we were encouraged in pursuing this investigation by finding that several of the authors who had previously published Tables of the Expansion of Metals differed widely in their results. These discrepancies, having reference to some metals most extensively used, might, we thought, be due either to the method employed, or the fact that metals of different degrees of purity had been experimented upon. Therefore, being sure of the purity of the metals that we intended to employ, we had recourse to a method, the accuracy of which, we trust, will appear satisfactory.

Owing to the difficulty of obtaining the metals in a pure state, in large quantities, we found it necessary to employ square bars, having a length of 60 millimètres by 10 millimètres in diameter, and devised the following process to determine with accuracy the expansion of such short bars. This we believe we have effected, as our apparatus will easily indicate an expansion amounting to the 50,000th part of an inch, or about the 2000th part of a millimètre.

¹ CHEMICAL NEWS, vol. III. p. 285.

Description of the Apparatus Employed in Determining the Expansion of Metals and other Bodies by Heat.

A piece of stone is let into a thick, strong wall (part of the basement of a large building), and very securely fixed, with a portion projecting out of the wall about $4\frac{1}{2}$ inches in thickness, and having a level surface of about 6 inches square, on which the body to be measured is placed; $2\frac{1}{2}$ inches above this a steel stud is firmly fixed, projecting from the face of the wall and ground exactly to fit the hole in a brass bush which is fixed in a lever. The steel stud serves as the fulcrum on which the lever moves freely, but without any shake. The lever is a long piece of oak, about 1 inch thick and $3\frac{1}{2}$ inches broad at the fulcrum, and having a long and short arm, the longer one being 34 times the length of the shorter one. The long arm is tapered in thickness and breadth from the fulcrum to the end, where it is about $\frac{1}{2}$ of an inch thick and $1\frac{3}{10}$ inches broad. The stone and the fulcrum are placed at such a distance from the termination of the wall as to allow the long arm of the lever to project a few inches beyond it. The steel fulcrum is so fixed as to cause the lever to move parallel to the face of the wall, at a distance of about $\frac{3}{4}$ ths of an inch from it. The lever is maintained in a horizontal position by a string carried up from the extremity of its longer arm to a steel bar, to the end of which the string is hooked. This bar is suspended like the needle of a mariner's compass, and has in the middle a conical hollow, which allows it to move freely up and down upon a steel pillar with a fine conical point. This is fixed to the wall, about 3 feet above the height of the long arm of the lever. The end opposite to that to which the long arm of the lever is attached by the string has a wire depending from it, on which weights may be placed sufficient to counterpoise the long arm and maintain the lever in a horizontal position.

Thus, it will be evident that if the bar of metal to be experimented upon be placed with one end on the stone and the other under the short arm, any elongation of the metal will produce a depression of the opposite end of the lever, and, on the contrary, as the metal contracts in cooling, the short arm will follow it and the long arm of the lever will rise, and, as it is 34 times longer, it will move through 34 times the distance. To prevent any unsteadiness in its movements, sufficient weight is attached to the counterpoise to cause the lever to press firmly on the metal bar to be measured, and thus, when heat is applied, the bar raises the short arm as it expands, and as it contracts, in cooling, is followed by the short arm with the utmost regularity.

We will now describe the method employed in reading off the space through which the long arm of the lever is moved by the expansion or contraction of the metal experimented upon. A circular hole of $1\frac{1}{4}$ inch diameter is made in the lever, the centre of which is 34 times further from the fulcrum than the end of the short arm; into this hole the object-glass of a small telescope is fitted. It will be evident, therefore, that if any object be placed a few yards in front of the object-glass its image will be received upon any surface placed behind it at a proper distance. This distance in the present case is 12 inches, when the rays of light from the object are brought to a focus. The eye-piece of a telescope, of considerable magnifying power, is used to receive the image upon. An ivory scale is supported in a vertical position upon a stand opposite to the object-glass, and, on looking through it with the eye-piece, the divisions of the rule are distinctly seen. A very fine line is placed

in the eye-piece, in the middle of the field. The eye-piece is attached to the end of the wall, and is provided with screws, one to adjust the focus, and the other to raise or lower it in a vertical direction, so that the line in the middle of the field may be brought into a coincidence with any of the divisions upon the rule. The rule used in making the experiments is 12 inches long, each inch divided into 60. These, though not distinguishable by the naked eye, are easily read by the aid of the object-glass and eye-piece at the distance required. To find the distance at which the rule should be placed to make one of the divisions equivalent to a change of $\frac{1}{100000}$ th of an inch, the following method is adopted:—The eye-piece was adjusted so that the line drawn across the field stood at zero on the rule. Then, by means of the adjusting screw, the eye-piece was raised exactly half an inch, the object-glass remaining unmoved. As the eye-piece is raised the spider line appears to traverse a certain number of the divisions. The number of divisions it ought to pass over by raising the eye-piece half an inch is between 367 and 368, and by placing the graduated rule about 14 feet from the eye, the spider line is seen to move from 0 to the 368th division. Then, as 368 to the half inch is equal to 736 to the inch, the line in traversing the space between any two divisions moves through $\frac{1}{736}$ th part of an inch. Now, in making experiments in the expansion of bodies, the object-glass moves, while the eye-piece remains stationary. If we suppose, then, that under the short arm of the lever a bar is placed and heat is applied sufficient to elongate it $\frac{1}{100000}$ th part of an inch, the spider line will appear to ascend from the division it stood at to the one above it, because the long arm being 34 times the length of the short one, it will move through 34 times the space. We must, therefore, multiply 736, the number of divisions in an inch, by 34, which gives 25,024; so that an elevation or depression of the object-glass sufficient to cause the spider line to traverse one division of the rule, is equivalent, in round numbers, to a change in length of the bar of $\frac{1}{250000}$ th of an inch. With a little practice, the eye can readily estimate a change in the position of the spider line of one-half or even one-quarter of the space between two divisions, thus reading off the $\frac{1}{100000}$ th of an inch.

We will now describe the method of raising the temperature of a bar from its natural temperature to 90° Centigrade. A tin vessel, about 2 inches square, and of such a depth as to contain sufficient water to immerse the bar, is placed beneath the short arm of the lever. The bottom of the vessel is of brass, $\frac{1}{4}$ th of an inch in thickness. At the angle furthest from the bar, and close to the bottom, a tube is inserted to admit steam; and at the angle nearest to the bar, and at the surface of the water, is an outlet to carry off the overflow. The vessel is covered with a lid, in which are two apertures,—one to allow the end of the bar to come through, and the other for the insertion of a standard thermometer, divided into tenths. The experiments were made in the following manner:—The bar to be tried is placed in the vessel, with the short arm of the lever resting upon its upper end. One operator then pours water into the vessel and allows it to run out till the thermometer descends to a fixed point. At this instant another operator sets the spider line at zero. The tube at the lower angle of the vessel is then connected with a flask in which steam is generated, which is passed by this tube through the water in the vessel until it is raised to the temperature of 90°, at which it is maintained until the bar arrives at a fixed temperature. The degree of expansion is then read off by the observer at the eye-piece. The tube is

then disconnected and cold water is passed through the vessel repeatedly until a fixed temperature is again obtained. Another reading is then taken. These experiments are several times repeated until a number of coördinate results are obtained. To attain this we had no difficulty, as our readings varied only a few hundred-thousandths of an inch from one another, as will be seen by the series of experiments annexed:—

These results, however, require a deduction to be made from them on account of the expansion which takes place in the brass bottom of the vessel, and also in the stone upon which it rests. To ascertain this exactly the following experiments were made:—A rod of the same steel, nearly ten times the length of the short bar, is suspended by a steel pin inserted in the wall at such a height as to allow the short end of the lever to rest upon another steel pin, passing through the lower extremity of the long bar. It is enclosed in a glass tube, extending a few inches above the upper end of the bar, and open at the top. It is closed at the bottom, with the exception of an opening for the admission of a jet of steam. The steel bar, thus suspended by the two steel points, does not partake of the expansion of the tube or any other part of the apparatus. It is then submitted alternately to the action of steam and cold water, and the expansion, observed as before, gave us the following results:—

Heating from 16·5° to 100°.

	1st.	3rd.	5th.
16·5° =	625	624	618

Ditto of the above long bar for 100° . . 61·7

Correction 20·2 (say 20·6)

From these figures it will be seen that it is necessary to deduct 20 from the observed expansion of the short steel bar from 0° to 100°, which excess we found to be due to the expansion of the bottom of the tin vessel, together with that of the stone upon which it rested. The correctness of deducting 20 from the results of all observations upon the short bars for the expansion of 100° Centigrade was further confirmed by employing several different modes of investigation.

Before giving the results, we think it our duty to make one or two remarks upon the apparatus:—

1st. If the plaited string which connects the lever with the counterpoise should stretch with the weight upon it, or be contracted or expanded by change of temperature, no effect is produced in the position of the lever during an experiment, for the action of the counterpoise is simply to keep the short arm upon the bar experimented upon, and the pressure still keeps it there, however the length of the string may vary. This was determined by direct experiment.

2nd. The spider line of the eye-piece always remains fixed across the centre of the field, so that the observer always looks through the centre of the lens; but it happens sometimes that the centre of the object-glass is not exactly opposite the eye-piece. The expansion of the bar may have raised it so far that the observer may be looking through the object-glass near its edge. This does not, however, sensibly affect the correctness of the reading, and repeated experiments have proved that it does not entail the error of $\frac{1}{10000}$ th of an inch. By proper precaution, however, this error may be avoided, as there are only one or two metals that expand so much as to throw the centre of the object-glass much above or below the spider line.

3rd. By taking the precaution of introducing the jet of steam at the bottom of the vessel, and at the point most distant from the bar, and allowing the overflow to pass out at the angle nearest to the bar, we secured perfect uniformity in the temperature of the water in every part, except in the immediate neighbourhood of the opening through which the steam was introduced. This was carefully ascertained in the course of our experiments, by placing our standard thermometer in various parts of the water. When an open tube was used, the steam was passed through till a fixed temperature of 100° was obtained at its open extremity.

Lastly. In making the experiments we have observed that the expansion for each 10° has been in the same ratio as that from zero to 100°.

(To be continued.)

On the Amounts of Lead contained in some Silver Coins, by Messrs. CHARLES W. ELIOT and FRANK H. STOREY.

FROM our experiments upon the impurities of commercial zinc,¹ we found that this metal almost invariably contains lead. In the preparation of silver at the United States Mint, zinc is used for the purpose of reducing chloride of silver,² and a sample of zinc similar to that used at the Mint, which we examined, yielded half of one per cent. of lead. The question naturally suggested itself whether lead might not thus find its way into American silver coin, and to determine this point we have analysed several American coins, as specified in the following table. For the sake of comparison we subsequently examined the other coins therein enumerated.

On the supposition that the zinc used in the reduction of the silver is the source of the lead in the American coin, it is easy to calculate the amount of lead which would thus find its way into the coin, since the quantity

¹ Memoirs of the American Academy, 1860 [N. S.], viii. 57.

³ Columns (a), (b), and (c) contain the results of a supplementary series of experiments, made merely to control the results given in columns (4) and (5). (Vid. infra.)

⁴ The solution of this fine silver in nitric acid became blue when neutralised with ammonia. The filtrate from the mixed precipitate of sulphate of lead and gold contained a decided trace of copper and a fainter trace of iron. The solution of sulphate of soda, from which the sulphuric acid of col. (3) was determined, exhibited a slightly yellowish-light-brown color, nothing similar to which occurred in any of the other experiments. A slight black residue remained when this silver was dissolved in nitric acid, and a trace of gold was detected in the residue.

of zinc used in reducing a given weight of silver, and the per cent. of lead which that zinc may be expected to contain, are both known quantities. Professor Booth⁵ says that an excess of zinc is required to insure total and rapid reduction, and Wilson⁶ states that two equivalents of zinc are used, in practice, for each equivalent of silver. Our memoir, already cited, gives the per cents. of lead found in two specimens of Vieille Montagne zinc. The standard of the American silver coin is $\frac{1}{10}$ silver and $\frac{1}{10}$ copper, and the weight of fifty cents' worth of this alloy, in either half-dimes, dimes, quarters, or a half-dollar, has been 192 grains = 12.433 grammes, since the year 1853.⁷

Fine silver in the half-dollar . . . 11.190 gram.
Zinc used in reducing 11.19 gram. silver . 6.742 "
Amount of lead in 6.742 gram. zinc, if the zinc contains 0.292 per cent. of lead⁸ . 0.0197 "
Amount of lead in 6.742 gram. zinc, if the zinc contains 0.494 per cent. of lead⁸ . 0.0333 "

If zinc of the best quality (containing 0.292 per cent. of lead) had been used, the silver coin would have contained 0.158 per cent. of lead; if the second quality (containing 0.494 per cent. of lead) has been employed, the coin may contain 0.268 per cent. of lead. Between these two limits all our determinations of lead in American silver will be found to lie.

In offering this explanation of the occurrence of lead in American silver coin, we would by no means affirm that the zinc is the exclusive source of this impurity, for it is not at all improbable that a portion of the lead is derived from the leaden vats in which the reduction of the chloride of silver is effected, or from the sulphuric acid which is used to excite the reaction.

The method of analysis employed was as follows:—The coin having been dissolved in moderately strong, pure nitric acid, the cooled solution was treated with an excess of a solution of pure caustic ammonia, added by small portions,—no notice being taken of the small, dark-coloured residue (AgS, etc.) insoluble in nitric acid. The precipitated oxide of silver was re-dissolved in nitric acid, enough of the latter being added to render the solution distinctly acid. The whole was then heated in a water-bath, and a strong solution of pure chloride of ammonium added, until chloride of silver was no longer precipitated, care being taken to avoid adding an unnecessary excess of chloride of ammonium. It will be seen that the chloride of silver was thus precipitated in presence of a large excess of nitrate of ammonia; and since chloride of lead is readily soluble in a solution of nitrate of ammonia,⁹ any lead which the coin may have contained would remain in solution. It may be mentioned in passing, that the small amount of chloride of silver which, as has already been stated by Mulder,¹⁰ is retained in solution by nitrate of ammonia—especially by hot solutions—did not interfere in the least with the subsequent steps of the analysis, or in any way to influence the amount of lead obtained. The precipitated chloride of silver was collected upon a filter, and thoroughly washed with hot water, the lumps of chloride of silver being broken down as much as possible with a glass rod. The filtrate and wash waters were evaporated in a porcelain dish to the consistence of a thin syrup, and

¹⁰ "Die Silber-Probirmethode," (Leipzig, 1859), p. 28.

then transferred to a flask of hard German glass, in which the evaporation was continued until the nitrate of ammonia had been entirely destroyed. This operation requires care in the application of the heat, lest violent decomposition of the nitrate of ammonia ensue, and portions of the substance be projected from the flask. When properly conducted, the process goes on tranquilly, and no loss occurs. The residue, consisting of nitrate of copper, together with nitrate of lead, and more or less gold, should be washed with hot water into a porcelain dish, where it is mixed with a slight excess of pure sulphuric acid. It may be necessary to use a little nitric acid to dissolve the last portions of the substance in the flask. The mixture is then evaporated over the water-bath until it has become almost entirely dry, or until it no longer exhibits any tendency to effervesce. It is then somewhat more strongly heated on a sand-bath, until all the free sulphuric acid has been driven off—that is, until fumes of sulphuric acid are no longer perceptible. The necessity of thoroughly evaporating this mixture cannot be too strongly insisted upon, for a solution of gold in sulphuric acid¹¹ is formed when the mixed nitrates, &c., are treated with sulphuric acid, and unless this compound be entirely destroyed by heating, it will be subsequently decomposed when water is added, and give rise to a precipitate of metallic gold, in a condition so finely divided that it cannot be separated by filtering. The occurrence of this precipitate would ruin the analysis. We at first sought to prevent the formation of this solution of gold in sulphuric acid by heating very strongly the residue left in the flask after all the nitrate of ammonia had been decomposed, until the escape of nitrous fumes had entirely ceased, and the nitrate of copper was decomposed. We then treated the mass with pure dilute nitric acid, and filtered off the solution from the gold which had been deposited and from any chloride of silver which had been dissolved by the nitrate of ammonia, with the intention of determining the lead directly, by precipitating it as sulphate from this solution after evaporation with sulphuric acid. It was found, however, that a large portion of the gold-salt escaped decomposition in the flask, the yellow solution of sulphate of gold being formed almost as abundantly after this treatment as when the flask was not heated so strongly; and since in this method there is great risk of fracturing the vessel from drops of acid condensing in its neck and flowing down upon the hot portion, it can in no wise be recommended. A perfectly dry mixture of sulphate of copper, sulphate of lead, and metallic gold having been obtained, it is treated with distilled water, a considerable quantity of the latter being added at once, and the mixture quickly stirred to prevent the sulphate of copper from forming a hard cake as it becomes hydrated. As soon as the sulphate of copper is completely dissolved, a small quantity of pure sulphuric acid is to be added to the solution, and the latter set aside for at least forty-eight hours. The precipitate, consisting of sulphate of lead and metallic gold, was then collected upon a small Swedish filter and washed, first with dilute sulphuric acid to remove the sulphate of copper, and subsequently with alcohol, until no trace of free sulphuric acid remained. After drying, the precipitate of sulphate of lead and gold, with the filter cut into small pieces, was transferred to a beaker glass, and the whole was then digested with pure bicarbonate of soda¹² (prepared from

the oxalate), during at least forty-eight hours. The sulphate of soda formed by this operation was then filtered off from the carbonate of lead and metallic gold, and the amount of sulphuric acid which it contained determined by precipitation with chloride of barium in the usual way. From the amounts of sulphate of baryta thus obtained, recorded in column 3 of the table, the amounts of lead (col. 4) in the mixed precipitates of sulphate of lead and gold were calculated.

The carbonate of lead, mixed with bits of paper and gold, above mentioned, was now dissolved in dilute nitric acid, the solution evaporated with sulphuric acid until all the nitric acid had been expelled, subsequently treated with water acidified with sulphuric acid, and, after standing for forty-eight hours, collected upon a tarred filter, washed with dilute sulphuric acid and alcohol, dried at 100°, and weighed. The results may be found in column (a) of the table.

The re-agents used in the foregoing operations were all chemically pure. A special experiment was moreover made, in which portions of the nitric acid, ammonia, chloride of ammonium, and sulphuric acid used, twice as large as any which were actually employed in the analysis of either of our samples of coin, were evaporated together, and subjected to a course of treatment identical with that which the solutions of coin were forced to undergo; but not a trace of sulphate of lead, or of any precipitate, other than a few light and utterly insignificant floating flocks, probably alumina, could be detected as the result of this trial.

That our process is sufficiently accurate to exhibit *all* the lead which the samples of coin examined really contained, we do not think probable. All of the sources of error to which the process, when properly conducted, is subject, tend to cause a slight loss of lead. Thus, in the first place, it is scarcely possible that the last traces of chloride of lead can be removed by washing from the caseous precipitate of chloride of silver,¹³ which precipitate is in enormous mass as compared with the amount of chloride of lead; and again, the first precipitate of sulphate of lead, mixed with gold, which is obtained after evaporation with sulphuric acid, occurs in so finely divided a state that it is exceedingly difficult to prevent loss by the passing of a portion of it through the pores of the filter upon which the precipitate is collected. To one unused to the process, it might seem as if the last traces of sulphuric acid could hardly be removed from this precipitate by washing with alcohol. We have satisfied ourselves, however, that this is easily effected, and that this seeming source of error is, in reality, entirely insignificant; at any rate, the results given in columns (a), (b), and (c) are in no way influenced by this imaginary error. It may not be amiss to observe, that we have been particularly scrupulous with regard to the treatment of the above-mentioned precipitate, having in every instance continued to wash it with alcohol long after any reaction of sulphuric acid could be detected. It should also here be stated, that the results in which we ourselves place the most confidence are those obtained by determining the amount of sulphuric acid in the mixed precipitate of sulphate of lead and gold (see cols. (3), (4), and (5) of the table), for columns (a), (b), and (c) contain the results of a secondary process liable to all the accumulated errors of a long series of operations. Moreover, the final precipitate of sulphate of lead is very finely divided, and, like the first precipitate, liable to pass through the pores of the filter, as has been

¹¹ Compare Pelletier, "Ann. Ch. et Phys." [2], xv. 12.

previously explained. This second series of experiments has been carried out, not from any expectation that the results would closely agree with those of the first series, but merely to control the latter to a certain extent, and to remove any objection which might be made to the indirect method by which they were obtained. Since the possible inaccuracies of the process tend to a loss of lead, we are confident that the amounts of lead we have obtained are in no instance greater than those really existing in the coin.

The precipitates of pure sulphate of lead (column (a) of the table) were, in every instance, reduced on charcoal with carbonate of soda, and the button of lead obtained carefully tested for silver, of which none could be detected in any case; nor did the metal exhibit any reactions, other than those of pure lead.

(To be continued.)

TECHNICAL CHEMISTRY.

On the Composition of Cast Iron and Steel, by M. E. FREMY.

THE phenomena determining the production of steel have always occupied the attention of chemists and manufacturers, but at the present moment the study of this question has assumed an exceptional importance. In fact, the construction of machines and the manufacture of fire-arms are extending the applications of steel, and necessitate its production as economically as possible consistently with preserving its valuable properties. To resolve this problem, of so much interest to metallurgical industry, chemistry ought to throw fresh light on the theoretical questions relating to the production of steel, and to free manufacture from the uncertainty and empirical methods which retard its due development.

The theories hitherto proposed to explain the phenomena of steeling are evidently inadequate to guide the metallurgist wishing to produce steel either by the cementation of iron by charcoal or by decarburising cast iron by special puddling.

Thus, the influence of manganese and that of tungsten in the process of steeling is not easily explained. The utility of nitrogenised organic substances and certain saline matters in aiding solution is denied by experienced metallurgists. Some are of opinion that the best quality of cemented steel is obtained by the action of carbon on pure iron; others, that cementation can take place only under the influence of the nitrogen of the air. In either case, theory does not tell us why certain irons yield the best steel, while others, to all appearance as pure, produce a very inferior quality. It is well known that the difficulties in the fabrication of steel obtained by puddling are such as often to discourage the most skilful manufacturers.

This uncertainty in the methods of steeling is found likewise in the theories proposed for explaining the production of steel. Some chemists are of opinion that solid carbon acts directly on iron, penetrates the metal, and, circulating in its mass, converts it into steel. Others, among whom Leplay and Laurent are conspicuous, believe that cementation is invariably owing to the action of a gaseous carburetted compound on iron. Laurent goes so far even as to say that in the cementation-boxes the vapour of the volatilised carbon effects the acieration.

The action exercised on iron by cyanides widens the field of the theory of cementation. A familiar experiment in chemistry has been utilised in practice: it consists in converting iron into steel by heating it with an alkaline cyanide or ferrocyanide. And, again, M. Caron, in a recent and interesting communication to the Academy, states that cyanide of ammonium, which is formed in the cementation-boxes, acts on iron like alkaline cyanides and rapidly converts it into steel.

The papers published on the subject of acieration have, doubtless, enriched science with many new and important facts; above all, they have particularised the circumstances which appear to determine this process most readily, but they have thrown no new light on the theoretical questions relating to the chemical constitution of steel. The writers still aver that steel is a carburet of iron, which they place chemically between iron and cast iron.

My opinion as to the composition of steel differs entirely from those hitherto accepted. I hope to be able to prove that steel is not a carburet of iron, and that there exists a series of steels resulting from the combination of iron with metalloids, metals, and even with cyanuretted bodies.

I am not acquainted with a single unequivocal experiment tending to show that steel is a combination of pure carbon and iron. Minute proportions of foreign bodies, not always detectable by analysis, can modify the properties of iron. When it is proposed to study the action of pure carbon on iron, there are necessarily other bodies present besides those whose mutual action we desire to determine. Without referring to the impurities taken up from the crucible, there are the influence of the gases from the furnace, which penetrate the apparatus; the action of the atmospheric elements which the charcoal does not absorb; or the presence of the various substances contained in the charcoal itself,—all of which circumstances are wholly disregarded.

In an experiment with diamond-dust, which I shall presently state, the influence of foreign bodies have been equally unheeded.

I shall now recal the fact I have already submitted to the Academy, which is, that steel, when dissolved in acids, leaves a residue in no point resembling pure carbon, and which, by its properties and composition, is nearly allied to certain cyanuretted products; thus, both synthetical and analytical experiments are far from proving that steel contains nothing but carbon and iron.

To determine the true constitution of steel, and to ascertain whether there does not exist a series of bodies differing in composition, as tungsten steel differs from that of charcoal, yet allied by certain common properties, I propose to submit iron to the action of all the bodies capable of influencing the phenomenon of acieration.

I think that nitrogen ought to take the first place in this examination. Such was the object of my last communication to the Academy.¹

I have applied myself to free nitride of iron from the excess of metal it is capable of retaining, and to produce, as far as possible, a definite compound.

But in the nitration of iron, as in the carburisation of this metal, there are different degrees. Before forming under the influence of nitrogen, the scales which come off, and which, according to my experiments, contain 9.5 per cent. of nitrogen, the general properties of the metal undergo profound modifications; while preserving a

¹ CHEMICAL NEWS, Vol. III. p. 276.

certain malleability, it becomes white and fibrous. The iron in this state is still metallic, but, nevertheless, is strongly nitrogenised. It is this nitrogenised iron which I submit to the Academy, and which has undergone the processes connected with steeling which I am about to describe.

Desiring to study the successive or simultaneous action of nitrogen and carbon on iron, I was first obliged to find out a simple and easily-graduated method of carburisation as certain as the process for the nitration of iron by ammonia.

The action of illuminating gas on iron possesses all these advantages. In fact, I have proved that if dry coal-gas is passed at red heat during two hours on iron, I obtain a very regular carburisation, and the metal is converted into a gray cast iron, graphitic, very malleable, and in every way comparable to the best cast iron produced by wood charcoal. I present to the Academy a specimen of cast iron formed under these circumstances.

By employing ammonia and coal-gas, I possess two easily regulated processes, which enable me to study, either isolatedly or simultaneously, the action of ammonia and carbon on iron.

The result of my experiments is, that when iron is submitted to the action of coal-gas I obtain cast iron only; but when the carburetted gas is made to react on previously nitrogenised iron, the characteristics of steel are evident in the metallic compound. A very remarkable fact here appears, which is, that the properties of the steel in some measure depend on the quantity of nitrogen first imparted to the iron. If the nitration has not been carried on a sufficient time, the coal-gas, in acting upon iron, produces a body intermediate between steel and cast iron; if, on the contrary, the metal has undergone a sufficient degree of nitration, the gas produces a steel of magnificent grain. The specimens which I presented to the Academy were formed in this manner. I have thus been enabled to realise M. Despretz's anticipations, and to determine what influence nitride of iron exercises on the phenomena of steeling.

When, instead of making nitrogen and carbon react successively on the metal, I have passed a mixture of ammonia and lighting-gas on red-hot iron, the metal has immediately changed to steel, which varies with the relative proportions of the two gases.

In the experiments here described I believe I have for the first time produced steel by means of the successive action of two gases on iron,—one, ammoniacal gas, furnishing nitrogen; the other, lighting gas, furnishing carbon; and what appears to me to make the steel thus obtained still more interesting is, that with it cementation is no longer effected with wood charcoal, but with coal-gas. I ask metallurgists whether these experiments, which, in a theoretical point of view, throw light on the phenomenon of cementation, will not one day be practically utilised. Would it not be a curious circumstance in the cementation of iron were wood charcoal superseded by the products of the distillation of coal?

These facts establish positively the important part nitrogen plays in the phenomena of steeling. It remained for me to ascertain whether nitrogen, evidently a cementing agent, remains in the metallic compound, or whether its only use is to present carbon to the iron in a state favourable to chemical combination.

To resolve this interesting question, I submitted steel, obtained with ammonia and lighting gas, to the influence of the agent which could prove the presence of nitrogen

in steel with the greatest nicety,—viz., pure and dry hydrogen.

By heating in hydrogen some steel prepared in my laboratory, I immediately detected the presence of nitrogen in this metallic compound; for during the whole of the experiment it disengaged considerable quantities of ammonia.

After thus re-finding nitrogen in steel obtained by the action of ammonia and lighting-gas on iron, it became interesting to submit ordinary steel to the same proofs, and to ascertain whether these metallic compounds are equally nitrogenised.

To this end I have operated on steels of various sorts, all in high commercial estimation. My experiments were made successively on Jackson's French, Huntsmann's English, and Krupp's German steel.

(To be continued.)

On Artificial Guano, by Dr. ABRAHAM GESNER, F.G.S.

GUANO, so valuable a fertiliser, is chiefly composed of the excrements of sea fowls. Frequently it contains feathers, bones of fishes, humus, &c. It is very variable in composition, a circumstance that has been ascribed to the different kinds of food upon which the birds subsisted. Some guanos contain upwards of 25 per cent. of uric acid, in others that acid is almost entirely absent, and it is the same in regard to other acids, salts and alkalies. Ammonia usually enters largely into the best qualities of this fertiliser, and the presence of its carbonate is known by its odour. The oxalate, urate, and phosphate of ammonia and magnesia are almost always present with the phosphates of soda and lime, the phosphates having been derived from the bones of the fish upon which the birds fed. In the supply of ammonia and of earthy and alkaline salts, guano is of the greatest value for plants cultivated for food. The food of the birds, from which the guano had been deposited has been certain fish that fed upon other fish, the food of which was marine plants, or animalculæ. The origin of this fertiliser is therefore found in marine plants and animals.

The writer has obtained a product analogous to the true guano, and one nearly, if not quite, equal in its value for fertilising purposes. Chemical and mechanical means have been applied to the marine *fuci* and fishes and fish offal until an artificial guano has been obtained. The sources of the alkaline carbonate, chloride of sodium and organic matter have been found in marine plants, the phosphates and carbonates of lime and ammonia in the bones of flesh and fishes, and after many experiments, carefully performed, they have been combined so as to form a cheap and portable manure. At Long Island, in the State of New York, *menhaden* are manufactured into manure: the oil, which is very offensive, being extracted from the fish and employed for common purposes.

Having visited a great number of the fishing establishments of the Provinces of New Brunswick, Nova Scotia, Newfoundland, and the islands and coasts of the Gulf of St. Lawrence and Labrador, the writer obtained a knowledge of the vast quantity of fish and flesh offal annually thrown into the sea, or otherwise lost to every useful purpose. The garbage thrown overboard yearly from vessels fishing on the banks of Newfoundland, if properly preserved and manufactured, with the annual growth of sea-weeds upon the shore, would fertilise the

entire cultivated surface of the Eastern States and British Provinces; still the amount of animal matter thus referred to is far less than that produced by the inshore fisheries.

To the foregoing may be added the enormous quantities of *mytili* and other shellfish growing upon the shore, and which are not less applicable for the manufacture of artificial guano than the offal of the finny tribes. At many places on the shores fish are met with in such abundance that they are employed by the fishermen to manure the small patches of ground some of them cultivate. At the principal fishing stations, the refuse garbage and bones alone would supply a manufactory, and with good management, and the use of kelp, the offal may be transported from place to place without inconvenience. Like the bones of terrestrial animals, the inorganic matter, or ash of the bones of fishes consists in the greater part of the phosphates of lime, or bone phosphate, with carbonate of lime, the fertilising properties of which are well understood. Few soils preserve their fertility for any length of time. Every crop removes from the earth certain elements, which it is the business of the farmer to restore, and for that purpose no manure is better adapted than guano, either natural or artificial.—*Scientific American*.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Weekly Evening Meeting.

WILLIAM ROBERT GROVE, Esq., M.A., Q.C., F.R.S.,
Vice-President, in the Chair.

On the Application of the Law of the Conservation of Force to Organic Nature, by Professor HELMHOLTZ, F.R.S.

THE most important progress in natural philosophy by which the present century is distinguished, has been the discovery of a general law which embraces and rules all the various branches of physics and chemistry. This law is of as much importance for the highest speculations on the nature of forces as for immediate and practical questions in the construction of machines. This law at present is commonly known by the name of "the principle of conservation of force." It might be better perhaps to call it, with Mr. Rankine, "the conservation of energy," because it does not relate to that which we call commonly *intensity* of force. It does not mean that the intensity of the natural force is constant; but it relates more to the whole amount of power which can be gained by any natural process, and by which a certain amount of work can be done. For example: if we apply this law to gravity, it does not mean, what is strictly and undoubtedly true, that the intensity of the gravity of any given body is the same as often as the body is brought back to the same distance from the centre of the earth. Or with regard to the other elementary forces of nature—for example, chemical force: when two chemical elements come together, so that they influence each other, either from a distance or by immediate contact, they will always exert the same force upon each other—the same force both in intensity and in its direction and in its quantity. This other law, indeed, is true; but it is not the same as the principle of conservation of force. We may express the meaning of the law of conservation of force by saying that every force of nature, when it effects any alteration, loses and exhausts its faculty to effect the same alteration a second time. But while, by every alteration in nature, that force which has been the cause of this alteration is exhausted, there is always

another force which gains as much power of producing new alterations in nature as the first has lost. Although, therefore, it is the nature of all inorganic forces to become exhausted by their own working, the power of the whole system in which these alterations take place is neither exhausted nor increased in quantity, but only changed in form. Some special examples will enable you better to understand this law than any general theories. We will begin with gravity; that most general force, which not only exerts its influence over the whole universe, but which at the same time gives the means of moving to a great number of our machines. Clocks and smaller machines, you know, are often set in motion by a weight. The same is really the case with water-mills. Water-mills are driven by falling water; and it is the gravity, the weight of the falling water, which moves the mill. Now you know that by water-mills, or by a falling weight, every machine can be put in motion; and that by these motive powers every sort of work can be done which can be done at all by any machine. You see, therefore, that the weight of a heavy body, either solid or fluid, which descends from a higher place to a lower place is a motive power, and can do every sort of mechanical work. Now if the weight has fallen down to the earth, then it has the same amount of gravity, the same intensity of gravity; but its power to move, its power to work, is exhausted. It must become again raised before it can work anew. In this sense, therefore, I say that the faculty of producing new work is exhausted—is lost; and this is true of every power of nature when this power has produced alteration. Hence, therefore, the faculty of producing work, of doing work, does not depend upon the intensity of gravity. The intensity of gravity may be the same, the weight may be in a higher position or in a lower position, but the power to work may be quite different. The power of a weight to work, or the amount of work which can be produced by a weight, is measured by the product of the height to which it is raised and the weight itself. Therefore our common measure is foot-pound; that is, the product of the number of feet and the number of pounds. Now, we can by the force of a falling weight raise another weight; as, for example, the falling water in a water-mill may raise the weight of a hammer. Therefore it can be shown that the work of the raised hammer, expressed in foot-pounds, that is, the weight of the hammer multiplied by the height expressed in feet to which it is raised,—that this amount of work cannot be greater than the product of the weight of water which is falling down, and the height from which it fell down. Now we have another form of motive power, of mechanical motive power; that is, velocity. The velocity of any body in this sense, if it is producing work, is called *vis viva*, or living force, of that body. You will find many examples of it. Take the ball of a gun. If it is shot off, and has a great velocity, it has an immense power of destroying; and if it has lost its velocity, it is quite a harmless thing. The great power it has depends only on its velocity. In the same sense, the velocity of the air, the velocity of the wind, is motive power; for it can drive windmills, and by the machinery of the windmills it can do every kind of mechanical work. Therefore, you see that also velocity in itself is a motive force.

Take a pendulum which swings to and fro. If the pendulum is raised to the side, the weight is raised up; it is a little higher than when it hangs straightly down, perpendicular. Now if you let it fall, and it comes to its position of equilibrium, it has gained a certain velocity. Therefore, at first, you had motive power in the form of a raised weight. If the pendulum comes again to the position of equilibrium, you have motive power in the form of *vis viva*, in the form of velocity, and then the pendulum goes again to the other side, and it ascends again till it loses its velocity; then again, *vis viva* or velocity is changed into elevation of the weight: so you see in every pendulum that the power of a raised weight can be changed into

velocity, and the velocity into the power of a raised weight. These two are equivalent.

Then take the elasticity of a bent spring. It can do work, it can move machines or watches. The cross-bow contains such springs. These springs of the watch and cross-bow are bent by the force of the human arm, and they become in that way reservoirs of mechanical power. The mechanical power which is communicated to them by the force of the human arm, afterwards is given out by a watch during the next day. It is spent by degrees to overpower the friction of the wheels. By the cross-bow, the power is spent suddenly. If the instrument is shot off, the whole amount of force which is communicated to the spring is then again communicated to the shaft, and gives it a great *vis viva*.

Now the elasticity of air can be a motive power in the same way as the elasticity of solid bodies; if air is compressed, it can move other bodies; let us take the air-gun; there the case is quite the same as with the cross-bow. The air is compressed by the force of the human arm; it becomes a reservoir of mechanical power; and if it is shot off, the power is communicated to the ball in the form of *vis viva*, and the ball has afterwards the same mechanical power as is communicated to the ball of a gun loaded with powder.

The elasticity of compressed gases is also the motive power of the mightiest of our engines, the steam-engine; but there the case is different. The machinery is moved by the force of the compressed vapours, but the vapours are not compressed by the force of the human arm, as in the case of the compressed air-gun. The compressed vapours are produced immediately in the interior of the boiler by the heat which is communicated to the boiler from the fuel.

You see, therefore, that in this case the heat comes in the place of the force of the human arm, so that we learn by this example, that heat is also a motive power. This part of the subject, the equivalence of heat as a motive power, with mechanical power, has been that branch of this subject which has excited the greatest interest, and has been the subject of deep research.

It may be considered as proved at present, that if heat produces mechanical power, that is, mechanical work, a certain amount of heat is always lost. On the other hand, heat can be also produced by mechanical power, namely, by friction and the concussion of unelastic bodies. You can bring a piece of iron into a high temperature, so that it becomes glowing and luminous, by only beating it continuously with a hammer. Now, if mechanical power is produced by heat, we always find that a certain amount of heat is lost; and this is proportional to the quantity of mechanical work produced by that heat. We measure mechanical work by foot-pounds, and the amount of heat we measure by the quantity of heat which is necessary to raise the temperature of one pound of water by one degree, taking the centigrade scale. The equivalent of heat has been determined by Mr. Joule, of Manchester. He found that one unit of heat, or that quantity of heat which is necessary for raising the temperature of a pound of water one degree centigrade, is equivalent to the mechanical work by which the same mass of water is raised to 423½ metres, or 1389 English feet. This is the mechanical equivalent of heat.

Hence, if we produce so much heat as is necessary for raising the temperature of one pound of water by one degree, then we must apply an amount of mechanical work equal to raising one pound of water 1389 English feet, and lose it for gaining again that heat.

By these considerations, it is proved, that heat cannot be a ponderable matter, but that it must be a motive power, because it is converted into motion or into mechanical power, and can be either produced by motion or mechanical power. Now, in the steam-engine we find

that heat is the origin of the motive power, but the heat is produced by burning fuel, and therefore the origin of the motive power is to be found in the fuel, that is, in the chemical forces of the fuel, and in the oxygen with which the fuel combines.

You see from this, that the chemical forces can produce mechanical work, and can be measured by the same units and by the same measures as any other mechanical force. We may consider the chemical forces as attractions, in this instance, as attraction of the carbon of the fuel for the oxygen of the air; and if this attraction unite the two bodies, it produces mechanical work just in the same way as the earth produces work, if it attract a heavy body. Now the conservation of force, of chemical force, is of great importance for our subject to-day, and it may be expressed in this way. If you have any quantity of chemical materials, and if you cause them to pass from one state into a second state, in any way, so that the amount of the materials at the beginning, and the amount of the materials at the end at this process be the same, then you will have always the same amount of work, of mechanical work or its equivalent, done during this process. Neither more nor less work can be done by the process. Commonly, no mechanical work in the common sense is done by chemical force, but usually it produces only heat; hence the amount of heat produced by any chemical process must be independent of the way in which that chemical process goes on. The way may be determined by the will of the experimenter as he likes.

We see, therefore, that the energy of every force in nature, can be measured by the same measure, by foot-pounds, and that the energy of the whole system of bodies which are not under the influence of any exterior body must be constant; that it cannot be lessened or increased by any change. Now the whole universe represents such a system of bodies endowed with different sorts of forces and of energy, and therefore we conclude from the facts I have brought before you, that the amount of working power, or the amount of energy in the whole system of the universe must remain the same, quite steady and unalterable whatever changes may go on in the universe. If we accept the hypothesis of Laplace, that in the first state the universe was formed by a chaos of nebulous matter, spread out through infinite space, then we must conclude, that at this time the only form of energy existing in this system was the attraction of gravitation, and it was therefore the same sort of energy as is possessed by a raised weight. Afterwards, astronomers suppose, this nebulous matter was conglomerated and aggregated to solid masses. Great quantities of this nebulous matter, possibly from a great distance, fell together, and thus their attraction, or the energy of their attraction, was destroyed, and hence heat must have been produced; and the facts we know at present are sufficient to enable us to calculate the amount of this heat, that is, of the whole heat which must have been produced during the whole process of conglomeration. This amount of heat is immensely great, so that it surpasses all our ideas and all the limits of our imagination. If we calculate this quantity of heat, and suppose that the sun contained at the same time the whole heat, and that the sun had the same specific heat as water, the sun would be heated to twenty-eight millions of degrees, that is, to a temperature surpassing all temperatures we know on earth; however, this temperature could not exist at any time in the sun, because the heat which was produced by the aggregation of the masses, must also be spent partially by radiation into space. I give only the result of these calculations in order that you may see from it what a great amount of heat could be produced in this way. The same process goes on also at present in the falling stars and meteors which come down to the earth from planetary spaces. Their velocity is destroyed by the friction of the air and by the concussion with the surface of the earth,

and we see how they become luminous, and if they are found on the earth, we find them hot.

The sun also at present is hotter than any heated body here on the earth. That is shown by the latest experiments made by Professors Kirchhoff and Bunsen, of Heidelberg, on the spectrum of the sun, by which it is proved, that in the atmosphere of the sun iron and other metals are contained as vapours which cannot be changed into vapours by any amount of heat on the earth.

Our earth contains a great amount of energy in the form of its interior heat. This part of its energy produces the volcanic phenomena; but it is without great influence upon the phenomena of the surface, because only a very small amount of this heat comes through. It can be calculated that the amount of heat which goes from the interior to the surface cannot raise the temperature of the surface any higher than the thirteenth part of a degree.

We have another power which produces motion on the surface of the earth. I mean the attraction of the sun and of the moon producing the tides.

All the other phenomena on the surface of the earth are produced by the radiations of the sun, by the sunbeams; and the greater part of those changes which occur on the surface of our earth, are caused by the heat of the sun. As the heat of the sun is distributed unequally over the surface, some parts of the atmosphere become heated more than other parts; the heated parts of the atmosphere rise up, and so winds and vapours are produced. They come down at first as clouds in the higher parts of the atmosphere, and then as rain upon the surface of the earth; they are collected as rivers, and go again down into the sea. So you see that all the meteorological phenomena of our earth are produced by the effect of the solar beams, by the heat of the sun.

The light of the sun is the cause of another series of phenomena, and the principal products of the light of the sun are plants, because plants can only grow with the help of the sun-light. It is only by the help of the sun-light, that they can produce the inflammable matter which is deposited in the bodies of plants, and which is extracted from the carbonic acid and the water contained in the atmosphere, and in the earth itself.

This may give you an idea of the sense and bearing of the general principle on which I purpose to speak. As many English philosophers have been occupied with working out the consequences of this most general and important principle for the theory of heat, for the energy of the solar system, for the construction of machines, you will hear these results better explained by your own countrymen; I shall abstain from entering further into this part of the subject. At the same time that Mr. Grove showed that every force of nature is capable of bringing into action every other force of nature, Mr. Joule, of Manchester, began to search for the value of the mechanical equivalent of heat, and to prove its constancy, principally guided by the more practical interests of engineering. The first exposition of the general principle was published in Germany by Mr. Mayer, of Heilbronn, in the year 1842. Mr. Mayer was a medical man, and much interested in the solution of physiological questions, and he found out the principle of the conservation of force guided by these physiological questions. At the same time also, I myself began to work on this subject. I published my researches a little later than Mr. Mayer, in 1845. Now, at first sight, it seems very remarkable and curious, that even physiologists should come to such a law. It appears more natural, that it should be detected by natural philosophers or engineers, as it was in England; but there is, indeed, a close connexion between both the fundamental questions of engineering and the fundamental questions of physiology with the conservation of force. For getting machines into motion, it is always necessary to have motive-power, either in water, fuel, or living animal matter. The constructors of machines, instruments, watches, within the

last century, who did not know the conservation of force, were induced to try if they could not keep a machine in motion without any expenditure for getting the motive power. Many of them worked for a long time very industriously to find out such a machine which would give perpetual motion, and produce any mechanical work which they liked. They called such a machine a perpetual mover. They thought they had an example of such a machine in the body of every animal. There, indeed, motive-power seemed to be produced every day without the help of any external mechanical force. They were not aware that eating could be connected with the production of mechanical power. Food, they believed, was wanting only to restore the little damages in the machine, or to keep off friction, like the fat which made the axles of wheels to run smoothly. Now, at first, by the mathematicians of the last century, the so-called principle of conservation of *vis viva* was detected, and it was shown that by the action of the purely mechanical powers, it was not possible to construct a perpetual mover; but it remained still doubtful if it would not be possible to do so by the interposition of heat, or electricity, or chemical force. At last, the general law of conservation of force was discovered, and stated, and established; and this law shows that also by the connection of mechanical powers with heat, with electricity, or with chemical force, no such machine can be constructed to give a perpetual motion, and to produce work from nothing.

We must consider the living bodies under the same point of view, and see how it stands with them. Now, if you compare the living body with a steam-engine, then you have the completest analogy. The living animals take in food that consists of inflammable substances, fat and the so-called hydrocarbons, as starch and sugar, and nitrogenous substances, as albumen, flesh, cheese, and so on. Living animals take in these inflammable substances and oxygen, the oxygen of the air, by respiration. Therefore, if you take, in the place of fat, starch, and sugar, coals or wood, and the oxygen of the air, you have the substances in the steam-engine. The living bodies give out carbonic acid and water; and then if we neglect very small quantities of more complicated matters which are too small to be reckoned here, they give up their nitrogen in the form of urea. Now, let us suppose that we take an animal on one day, and on any day afterwards; and let us suppose that this animal is of the same weight the first day and the second day, and that its body is composed quite in the same way on both days. During the time—the interval of time—between these two days the animal has taken in food and oxygen, and has given out carbonic acid, water and urea. Therefore, a certain quantity of inflammable substance, of nutriment, has combined with oxygen, and has produced nearly the same substances, the same combinations, which would be produced by burning the food in an open fire, at least, fat, sugar, starch, and so on; and those substances which contained no nitrogen would give us, quite in the same way, carbonic acid and water, if they are burnt in the open fire, as if they are burnt in the living body; only the oxidation in the living body goes on more slowly. The albuminous substances would give us the same substances, and also nitrogen, as if they were burnt in the fire. You may suppose, for making both cases equal, that the amount of urea which is produced in the body of the animal, may be changed without any very great development of heat, into carbonate of ammonia, and carbonate of ammonia may be burnt, and gives nitrogen, water, and carbonic acid. The amount of heat which would be produced by burning urea into carbonic acid and nitrogen, would be of no great value when compared with the great quantity of heat which is produced by burning the fat, the sugar, and the starch. Therefore we can change a certain amount of food into carbonic acid, water and nitrogen, either by burning the whole in the open fire, or by giving it to living animals as

food, and burning afterwards only the urea. In both cases we come to the same result.

Now, I have said that the conservation of force for chemical processes requires a fixed amount of mechanical work, or its equivalent, to be given out during this process; and the amount is exactly the same in whatever way the process may go on. And therefore we must conclude that by the animal as much work must be done, must be given out—the same equivalent of mechanical work—as by the chemical process of burning. Now let us remark that the mechanical work which is spent by an animal, and which is given to the external world, consists, firstly, in heat; and secondly, in real mechanical work. We have no other forms of work, or of equivalent of work, given out by living animals. If the animal is reposing, then the whole work must be given out in the form of heat; and therefore we must conclude that a reposing animal must produce as much heat as would be produced by burning its food. A small difference would remain for the urea; we must suppose that the urea produced by the animal is also burnt, and taken together with the heat immediately produced by the animal itself. Now we have experiments made upon this subject by the French philosophers Dulong and Desprez. They found that these two quantities of heat—the one emitted by burning, the other by the living animal—are nearly identical; at least, so far as could be established at that time, and with those previous researches which existed at that time. The heat which is produced by burning the materials of the food is not quite known even now. We want to have researches on the heat produced by the more complicated combinations which are used as food. Dulong and Desprez have calculated the heat according to the theoretical supposition of Lavoisier—which supposition is nearly right but not quite right—therefore there is a little doubt as to the amount of the heat, but experiments show that at least to the tenth part of that heat the quantities are really equal; and we may hope if we have better researches on the heat produced by burning the food, that these quantities will also be more equal than they were found to be by Dulong and Desprez.

Now, if the body be not reposing, but if muscular exertion take place, then also mechanical work is done. The mechanical work is very different, according to the different kinds of muscular exertion. If we walk only on a plane surface, we must overpower the resistance of friction and the resistance of the air; but these resistances are not so great that the work which we do by walking on a plane is of great amount. Our muscles can do work in very different ways. By the researches of Mr. Redtenbacher, the Director of the Polytechnic School of Carlsruhe, it is proved that the best method of getting the greatest amount of work from a human body is by the treadmill, that is, by going up a declivity. If we go up the declivity of a hill we raise the weight of our own body. In the treadmill the same work is done, only the mill goes always down, and the man on the mill remains in his place.

Now, we have researches on the amount of air which is taken in and of carbonic acid given out during such work in the treadmill, made by Dr. Edward Smith. He found that a most astonishing increase of respiration takes place during such work. Now you all know that if you go up a hill you are hindered in going too fast by the great frequency and the great difficulty of respiration. This, then, becomes far greater than by the greatest exertion of walking on a plane, and really the difficulty is produced by the great mechanical work which is done in the same time. Now, partly from the experiments of Dulong and Desprez, and partly from the experiments of Dr. Edward Smith, we can calculate that the human body, if it be in a reposing state, but not sleeping, consumes so much oxygen, and burns so much carbon and hydrogen, that during one hour so much heat is produced that the whole body, or a weight of water equal to the weight of the body, would be raised

in temperature one degree and two-tenths Centigrade (two degrees and two-tenths Fah.). Now Dr. Edward Smith found that, by going in the treadmill at such a rate, that, if he went up a hill at the same rate, he would have risen during one hour 1712 feet; that, during such a motion, he exhaled five times as much carbonic acid as in the quiet state, and ten times as much as in sleeping. Therefore, the amount of respiration was increased in a most remarkable way. If we now calculate these numbers we find that the quantity of heat which is produced during one hour of repose is one degree and two-tenths Centigrade, and that these are nearly equivalent to rising 1712 feet; so that, therefore, the amount of mechanical work done in a treadmill, or done in ascending a hill at a good rate, is equivalent to the whole amount of heat which is produced in a quiescent state. The whole amount of the decomposition in the living body is five times as great as in a reposing and wakeful state. Of these five quantities, one quantity is spent for mechanical work, and four-fifths remain in the form of heat. Always in ascending a hill, or in doing great mechanical work, you become hot, and the production of heat is extremely great, as you well know, without making particular experiments. Hence you see how much the decomposition in the body is increased by doing really mechanical work.

Now these measurements give us another analogy. We see that in ascending a mountain we produce heat and mechanical work, and that the fifth part of the equivalent of the work which is produced by the chemical process is really gained as mechanical work. Now, if we take our steam-engine, or a hot-air engine, or any other engine which is driven by heat in such a way that one body is heated and expands, and by the expansion other bodies are moved,—I say, if we take any thermo-dynamic engine, we find that the greatest amount of mechanical work which can be gained by chemical decomposition or chemical combination is only an eighth part of the equivalent of the chemical force, and seven-eighths of the whole are lost in the form of heat; and this amount of mechanical work can only be gained if we have the greatest difference of temperature which can be produced in such a machine. In the living body we have no great difference of temperature; and in the living body the amount of mechanical work which could be gained if the living body were a thermo-dynamic engine, like the steam-engine or the hot-air engine, would be much smaller than one-eighth. Really, we find from the great amount of work done, that the human body is in this way a better machine than the steam-engine, only its fuel is more expensive than the fuel of steam-engines.

There is another machine which changes chemical force into mechanical power; that is, the magneto-electric machine. By these magneto-electric machines a greater amount of electrical power can be changed into mechanical work than in our artificial thermo-dynamic machines. We produce an electric current by dissolving zinc in sulphuric acid, and liberating another oxidizable matter. Generally it is only the difference of the attraction of zinc for oxygen compared with the attraction of copper or nitrous acid for oxygen. In the human body we burn substances which contain carbon and hydrogen, and therefore the whole amount of attraction of carbon and hydrogen for oxygen is put into action to move the machine; and in this way the power of the living body is greater and more advantageous than the power of the magneto-electric machine.

Let us now consider what consequences must be drawn when we find that the laws of animal life agree with the law of the conservation of force, at least as far as we can judge at present regarding this subject. As yet we cannot prove that the work produced by living bodies is an exact equivalent of the chemical forces which have been set into action. It is not yet possible to determine the exact value of either of these quantities so accurately as will be done ultimately; but we may hope that at no distant time it

may be possible to determine this with greater accuracy. There is no difficulty opposed to this task. Even at present I think we may consider it as extremely probable that the law of the conservation of force holds good for living bodies.

Now we may ask, what follows from this fact as regards the nature of the forces which act in the living body?

The majority of the physiologists in the last century, and in the beginning of this century, were of opinion that the processes in living bodies were determined by one principal agent which they chose to call the "vital principle." The physical forces in the living body they supposed could be suspended or again set free at any moment, by the influence of the vital principle; and that by this means this agent could produce changes in the interior of the body, so that the health of the body would be thereby preserved or restored.

Now the conservation of force can exist only in those systems in which the forces in action (like all forces of inorganic nature) have always the same intensity and direction if the circumstances under which they act are the same. If it were possible to deprive any body of its gravity, and afterwards to restore its gravity, then, indeed, we should have the perpetual motion. Let the weight come down as long as it is heavy; let it rise if its gravity is lost; then you have produced mechanical work from nothing. Therefore this opinion that the chemical or mechanical power of the elements can be suspended or changed, or removed in the interior of the living body, must be given up if there is complete conservation of force.

There may be other agents acting in the living body, than those agents which act in the inorganic world; but those forces, as far as they cause chemical and mechanical influences in the body, must be quite of the same character as inorganic forces, in this at least, that their effects must be ruled by necessity, and must be always the same, when acting in the same conditions, and that there cannot exist any arbitrary choice in the direction of their actions.

This is that fundamental principle of physiology which I mentioned in the beginning of this discourse.

Still at the beginning of this century physiologists believed that it was the vital principle which caused the processes of life, and that it detracted from the dignity and nature of life, if any body expressed his belief that the blood was driven through the vessels by the mechanical action of the heart, or that respiration took place according to the common laws of the diffusion of gases.

The present generation, on the contrary, is hard at work to find out the real causes of the processes which go on in the living body. They do not suppose that there is any other difference between the chemical and mechanical actions in the living body, and out of it, than can be explained by the more complicated circumstances and conditions under which these actions take place; and we have seen that the law of the conservation of force legitimates this supposition. This law, moreover, shows the way in which this fundamental question, which has excited so many theoretical speculations, can be really and completely solved by experiment.

CORRESPONDENCE.

Tasmanian Wheat.

To the Editor of the CHEMICAL NEWS.

SIR,—Mr. Wentworth L. Scott is presuming too much upon the patience of your readers. Upon the strength of a certain facility in microscopic observation, and an unfortunate *cacòthes scribendi*, he considers it his vocation to favour the public with his opinion upon all and every subject connected with food and its adulteration. . . .

This being the case, it is not surprising that a long letter from this authority upon the products and resources of Tasmania, should appear in the *Society of Arts, Journal* appended to the interesting paper by Dr. Milligan. I am, however, astonished that you, Sir, should have occupied your valuable space with such nonsense. What is the meaning of the analysis of wheat which he there gives? The tabular form in which it is printed, together with the "100'000" placed at the foot of the column of figures, evidently show that they are per-centages, the united amounts making up 100 parts. If Mr. Scott had given us the figures as he found them, and left it to others to give their proper value to them, it would not have much mattered; but when an analyst prints in one column, water, 13'4, ash, 2'2, and then gives the constituents of that ash; next nitrogenous matter, 15'7, and nitrogen 2'5; then carbonous matter, 68'5, fat, 1'4, and starch, &c. 67'1. When all these and many more are placed in order, one under the other, and then nicely finished with a rule, and "100'000" beneath it as the sum of the whole, it is evident that Mr. Scott's arithmetic is at fault, and more than probable that his chemistry is not less so.—I am &c. F.C.S.

Burlington House, May 21, 1861.

[Our correspondent will see that we have omitted several paragraphs from his letter, which, being simply abusive, would be of interest to but few of our readers. Personalities do not strengthen a bad cause whilst they materially injure a good one.—ED. C. N.]

Composition of Oxen, Sheep, and Pigs.

To the Editor of the CHEMICAL NEWS.

SIR,—In your notice of the paper by Mr. Lawes and myself "On the Composition of Oxen, Sheep, and Pigs, and of their Increase whilst Fattening," which appears in the *CHEMICAL NEWS* of May 11, you remark on the fact, that, in the paper in question, "no particulars are afforded explanatory of the analytical methods employed, and of the general system of operating."

The fact is, that the paper you have noticed, is an abstract of numerous other papers which are referred to, and all the particulars in question, will be found in the *Philosophical Transactions*, Part xi., 1859.—I am, &c.

J. H. GILBERT.

Harpenden, St. Albans, May 15.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Reaction of Hyposulphite of Soda on Sulphate of Lime.—Diehl found (*Jahresbericht d. physikal. Verein zu Frankfurt*, 1859, s. 83) that sulphate of lime was dissolved when treated with a super-saturated solution of hyposulphite of soda. This solution depends, says the author, on the great disposition of the hyposulphites to form easily soluble double salts. When alcohol is added to the solution, the double salt formed separates out in the form of a heavy, oily fluid congealing into white crystalline needles, and mixed with the undissolved hyposulphite of soda. This behaviour of the hyposulphite of soda to sulphate of lime, offers a simple means of separating lime from the other insoluble alkaline earths in the form of sulphate. To separate sulphate of lime from sulphate of baryta, the mixture of these salts must be treated with a concentrated solution of the hyposulphite and gently warmed. To be quite certain that all the lime is extracted, the treatment with the hyposulphite should be repeated once or twice until the filtered solution gives no sign of lime when tested with oxalate of ammonia.

The undissolved sulphate of baryta may then be collected on a filter, washed with hot water, ignited and weighed; and the lime in the filtrate precipitated by oxalate of ammonia, and estimated in the usual way.

Action of Hyposulphite of Soda on Ferro- and Ferricyanides.—Diehl (*Ibid.*, s. 85) has further studied the action of hyposulphite of soda on ferrocyanogen compounds. The ferro- and ferricyanides of copper, lead, silver, and mercury, he finds to be soluble in a solution of the hyposulphite; while the corresponding compounds of zinc, manganese, cobalt, nickel, cadmium, and tin, are insoluble. This reaction, the author says, may be found useful in the qualitative separation of the above compounds.

Action of Phosphuretted Hydrogen on Salts of the Alkalies.—Winkler has made this the subject of a long investigation (*Chemisches Centralblatt.*, No. xviii. April 24, p. 285). In his experiments the author passed the non-spontaneously inflammable gas through dilute solutions of different salts, the object apparently being to see in what cases phosphoric acid was produced. With the chlorides of potassium, sodium, and ammonium, phosphoric acid was formed; but in no other cases was any obtained. The solutions were tested with molybdate of ammonia and hydrochloric acid; but in doubtful cases the author resorted to the other tests for phosphoric acid.

A solution of carbonate of soda absorbed the phosphuretted hydrogen, and evolved carbonic acid. At first the solution became cloudy, but the cloudiness soon disappeared. On the addition of the molybdate and hydrochloric acid, a bulky white precipitate was produced, which however redissolved when the mixture was shaken, and the fluid became of a bluish colour, which changed to a deep blue on being gently heated. The blue solution evaporated to dryness in a porcelain dish left a blue stain. Further investigation showed that the blue compound resulted from the partial deoxidation of molybdic acid. This led the author to try other means of detecting phosphoric acid, but he did not succeed in detecting any trace of that body. The experiment was repeated several times with the same results.

II. ORGANIC CHEMISTRY.

Acetylene.—New methods of preparing this gas (first discovered by Ed. Davy, and described by Berthelot, *CHEMICAL NEWS*, Vol. i., p. 287), by the decomposition of bromides of ethylene, have been discovered by Sawitsch at Paris and Miasnikoff at Kasan. (*Bulletin de la Société Chimique de Paris*, No. i., pp. 7—12.) The former passes the vapour of dibromated ethylene into an ammoniacal solution of cuprous oxide. A deep red-coloured powder falls, which, when dry, is very explosive. When heated with acids (sulphuric or hydrochloric) this fulminating powder gives off a gas which Sawitsch proved to be acetylene, C_2H_2 . Miasnikoff passes the vapour of bromated ethylene, C_2H_3Br (the bromide of acetyl of Gmelin, *Handbook*, Vol. ix., p. 187) once or twice through a hot and strong alcoholic solution of caustic potash and then into an ammoniacal solution of nitrate of silver. In this way a grey-coloured explosive powder is produced, which, when treated with dilute hydrochloric acid, also evolves acetylene. In both cases the formation of the acetylene is probably due to the splitting up of the bromide of acetyl into hydrobromic acid and acetylene. $C_2H_3Br = C_2H_2 + HBr$. Sawitsch also found that when bromide of acetyl is acted on in a closed vessel with amylate of sodium, bromide of sodium, amyl alcohol, and acetylene are formed.

Both authors are engaged in following up their researches with others on the bromide of propylene in the hope of obtaining the homologue of acetylene, C_3H_4 . M. Morkow-

nikoff at Kasan has, indeed, succeeded in forming from that body a detonating silver compound, which, when treated with dilute hydrochloric acid yielded a gas which appeared to be the body sought for, and which he calls *allylene*. It will be a happy day for chemists when the nomenclature of their science becomes fixed.

Ethyl-lactic Acid.—Boutlerow found that when iodoform was acted on by ethylate of soda, besides acrylic acid, another acid, $C_{10}H_{10}O_6$, was formed, to which he gave the name valero-lactic acid. This acid he has since made out (*Bulletin de Société Chimique de Paris*, No. i. p. 9) to be identical with Wurtz's ethyl-lactic acid, obtained by treating the diethyl ether of lactic acid with an alkali. Having shown that this acid is easily attacked by hydriodic acid, with the formation of iodide of ethyl, the author remarks it is very probable that the action of hydriodic acid and its congeners offers a means of eliminating the different groups which replace typical but not basic hydrogen. The splitting up of various organic compounds (e.g. glucosides) under the influence of dilute acids, belongs to the same class of phenomena. The new acids obtained by Heints, the author thinks, may be split up by hydriodic acid into glycolic acid, and the iodides of their respective alcoholic radicals. M. Konat, Zaitzetz has already proved that the action of hydriodic on anisic acid (which Kolbe and the author regard as methyl-oxybenzoic or methyl-salicylic acid) iodide of methyl is formed; but his experiments are not yet completed.

Coloured Derivatives of Naphthalene.—M. Roussin has succeeded in preparing some colours from naphthalene, which it would appear may be used as dyes. Unfortunately the colours are the same as the aniline derivatives, but they may perhaps possess the advantage of greater stability. The first step, of course, is the preparation of nitro-naphthalene. This M. Roussin makes by heating on a water-bath a mixture of 2lbs. of naphthalene and 10lbs. of commercial nitric. The naphthalene melts, and remains swimming on the surface, so the flask requires to be shaken occasionally. Some vapours escape, and in time an oily layer of nitro-naphthalene forms at the bottom. The whole is then decanted, and the nitro-naphthalene, which immediately congeals, is well washed to remove the excess of acid. It is further purified by melting it once or twice, and pressing it between folds of blotting paper after it has cooled. Melted nitro-naphthalene runs through filtering-paper like water. The next step towards the colour is the preparation of naphthylamine. Six parts of hydrochloric acid and one of nitro-naphthalene are mixed in a flask, and enough granulated tin is added to reach the surface of the mixture. It is then heated on a water-bath, the flask being shaken occasionally. In a few minutes a strong re-action takes place, the nitro-naphthalene disappears, and the mixture becomes limpid. It is then decanted into an earthen pan containing hydrochloric acid, whereupon the whole becomes nearly solid by the crystallization of the hydrochlorate of naphthylamine. The crystalline mass is drained on a cloth, and then strongly pressed. It is further purified by solution in boiling water, adding sulphide ammonium to precipitate any tin, and filtering while hot. The hydrochlorate crystallizes on cooling.

On mixing a colourless solution of this hydrochlorate and another of nitrate of potash, a pomegranate-red precipitate falls, which is completely insoluble in water. The application of this colour to dyeing is very simple. The skeins of silk are first dipped in a solution of the hydrochlorate of naphthalene, then wrung, afterwards immersed in a bath of nitrate of potash, and then rinsed as usual. Shades of colour, from a faint blush to a deep maroon, are procured according to the strength of the solutions. The colour is unchangeable in the light, and is not attacked by any bleaching agent. Its permanency, indeed, according to the author, is marvellous.

MISCELLANEOUS.

Royal Institution.—The following is the arrangement of Lectures for the ensuing week:—Tuesday, May 28, at 3 o'clock, Mr. John Hullah, "On the History of Modern Music." Thursday, May 30, 3 o'clock, Mr. W. Pengelly, "On the Devonian Age of the World." Friday, May 31, 8 o'clock, Dr. W. V. Waller, F.R.S., "On the Nutrition and Reparation of Nerves." Saturday, June 1, 3 o'clock, Professor Max Müller, "On the Science of Language."

Rock Oil as Fuel for Steam Engines.—An application of the Rock-oil of Pennsylvania for generating steam for motive power under steam engine boilers is exciting attention in the oil region. The following is a description of the apparatus used:—A series of iron pipes are laid in the fire arch of the boiler, which pipes are perforated in their upper surface with minute holes; the oil is supplied to those pipes by means of a force pump, aided by an air receiver, to preserve a constant pressure. A spray, so to speak, of oil is thus made to fill the space usually filled by the flame of wood or coal used to raise steam; this, once ignited, fills the fire arch and flues of the boiler, and maintains the desirable amount of heat in the boiler. If this fuel is not found to be too expensive, it will prove a good thing for the use of steamers on sea voyages. Its practical use has been proved, and it remains for chemists and others to test it on ships, &c., in a large way. There can be but little doubt that this oil will be found cheaper than coal for gas-making for lighting dwellings, streets, &c.; its price, under the influence of the vast supply raised, will soon come down to a matter of 15 or 20 cents per gallon.

A Fresh Water Spring at Sea.—Mr. W. A. Booth, the coast pilot of the revenue cutter *Harriet Lane*, reports the discovery of a boiling fresh water spring at sea, off the coast of Florida. He says the spring is situated twelve miles, north by east from St. Augustine, Fla., and eight miles off shore. It boils up with great force, and can be descried at a distance of two miles. When first seen it has the appearance of a breaker, and is generally avoided; but there is no danger in the vicinity, as there are five fathoms of water between it and the shore. Ten fathoms of water are found to the seaward, but no bottom can be reached with the deep sea lead and thirty fathoms of line at the spring itself. The water in the spring is fresh, and is by no means unpalatable. One peculiarity about this phenomenon is, that when the St. John's river is high, it boils up from six to eight feet above the level of the sea, and presents rather a forbidding appearance. This spring has doubtless deceived hundreds, who have hastily put about from, as they thought, imminent danger, and reported seeing a "rock with water breaking over it." The *Harriet Lane* has passed through it several times, and water has been drawn from it by a bucket thrown over the side, and when drank, no unpleasant taste or smell has been found.

Water as a Fuel in Making Iron.—The use of water as a fuel is now attracting a great deal of attention throughout the world. We translate the following from the *Revue Universelle*:—

"The vapour of water has already been utilised in metallurgy as an agent of oxidation in the roasting of certain minerals, particularly to facilitate the separation of the compounds of antimony and arsenic in metallic sulphurets. For several years, attempts have been made to employ the calorific power of the hydrogen contained in water; and it is in the same line of invention that Messrs. Maire and Vallee have sought to utilize water as a combustible in industrial furnaces, and particularly in metallurgical operations. Water, fed in a regulated and intermittent manner into a hot fire, is decomposed into oxygen and

hydrogen. The combustion of the latter, in presence of the atmospheric air (the oxygen of the water being employed in burning the carbon), produces a considerable heat in addition to that of the principal combustible. There results then a considerable augmentation of calorific without any addition of combustible, and, consequently, a more rapid fusion of metals and minerals, and an economy of fuel which the authors of the process state varies from 40 to 50 per cent. Experiments and calculations have demonstrated that the heat absorbed by the decomposition of water is less than that furnished by the combustion of the gaseous products of the water decomposed.

"The following is the manner in which Messrs. Maire and Vallee propose to apply their method to metallurgy. For a blast furnace, the water is led from a reservoir under a pressure of 1½ atmospheres in a pipe from A, the to A' the of an inch in diameter, which enters the tuyere at right angles at a distance from its end varying from 10 to 40 inches, and thus the water is blown, in the form of spray, into the centre of the fire."

We have strong doubts of the truth of the above statement which we have italicised, notwithstanding the high authority on which it is made.

ANSWERS TO CORRESPONDENTS.

"* In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

"* All Editorial Communications are to be addressed to Mr. CROOKES, and Advertisements and Business Communications to the PUBLISHERS, GARRYS, BORN & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

Vol. II. of the *CHEMICAL NEWS*, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1891, and will be complete in 26 numbers.

X. C. will receive all the information which he desires by applying to the Secretary.

S.—No silver compound will do. Try a solution of chloride of gold.

W. P.—The best way to remove starch from Printed Liama shawls when being re-dyed, is to steep the goods for two or three days in water at 70° F. to rot it away. Re-agents will injure the wool.

Blue Ink—S. Andrews.—Three drachms of Chinese Blue (ferrocyanide of iron) are to be ground up with one drachm of binoxalate of potash, and seven ounces of water. Usually a little gum (one drachm) is added to these quantities.

J. O.—The process is by no means exact, but it was given as a rough method of obtaining the approximate value without difficulty. Benzol boils at 176° F., whilst the accompanying hydrocarbons boil at temperatures above 212°. A mixture will, therefore, boil at a lower temperature the more benzol it contains. It would probably begin to boil at about 180°, and the boiling point would gradually rise to 200 or 300°; the benzol coming over at the commencement. For this reason, commercial benzoils are generally tested by trying how much comes over below 212°.

J. Allen.—The matter shall meet with immediate attention.

A. H. B.—Dissolving and fusing a given quantity will give the insoluble portion and moisture. For the sulphates and chlorides, estimate the acids in the usual way, and then, having ascertained what other bases are present, besides potash, unite the acids and bases together by calculation.

Kyfos writes:—"Mr. Challis, of Cambridge, having established, by the aid of the hydrodynamical equations, the fact that the phenomena of colours arise from modifications of ray pressures, how does the presence of a metal in the gas flames of Kirchhoff and Runnen's spectrum apparatus stifle the colours of the solar spectra, except the characteristic stripe or stripes of those metals present in the flames?"

THE CHEMICAL NEWS.

VOL. III. No. 78.—June 1, 1861.

MINERAL ADULTERATIONS IN PAPER.

PAPER made from the best descriptions of linen or cotton rags, and well sized with gelatine and a little alum, has always been distinguished by its superior strength and power of resisting the wear and tear of rough usage. The qualities usually employed for the manufacture of bank-notes, of cartridge envelopes, and the so-called "loan-paper," are of this class; they all bear some resemblance to parchment, and although somewhat transparent, are held in high estimation by reason of their considerable power of endurance. Of the unsized varieties, the linen paper made by Munktell, and commonly known as "Swedish filtering," is remarkable for purity; and, on account of its consisting wholly of pure vegetable fibre, and leaving consequently no more than an inappreciable amount of ash on burning, this make of paper has met with universal adoption by chemists, and is generally employed for filtering purposes in quantitative analysis.

The practice of introducing small quantities of mineral matter for the purpose of imparting a superior degree of hardness and opacity to writing paper, particularly cream-laid, is generally recognised, and may not be considered objectionable so long as the proportion employed is limited to the amount actually necessary to effect this end. Plaster of Paris and China clay are the materials usually selected, and, when used sparingly in paper-making, may be accounted necessary ingredients equally with the alum employed in the size. The advance in the price of rags during late years has, however, offered temptation, particularly to foreign manufacturers, to increase the proportion of the cheaper mineral constituents in their paper, and the amount has become so excessive that they must be regarded as adulterations.

Letters have been addressed to the *Times* during the past week, pointing out instances of this growing practice. Professor Penny, of Glasgow, states that he has found in several foreign samples quantities of fine white clay, amounting to upwards of 30 per cent., or nearly one-third of the weight of the paper. He further remarks, "that there is nothing in the general appearance of this clayed-paper to indicate the presence of so large a proportion of earthy matter; but when a sheet of it is slowly burned it leaves a grey, friable residue, having the form and apparently the texture of the original paper, and consisting almost entirely of clay." Several samples of British paper were found to contain notable quantities of sulphate of lime (gypsum, plaster of Paris). Cream-laid paper of foreign manufacture contained, according to the same author, from 29 to 33½ per cent. of clay, and printers' demy from 26 to nearly 31 per cent.

Mr. Francis Sutton, of Norwich, fully endorses the statements of Professor Penny, and alludes further to a serious evil likely to arise from the presence of an excessive amount of China clay in printing paper, that, inasmuch as this mineral kaolin consists of fine white

clay, associated with a considerable proportion of gritty silicious particles, these latter would lead to a more rapid destruction of the type employed for printing on such paper,—a result further to be anticipated on account of the inferior character of the foreign sizing.

The use of starch, so frequently employed in the paper mills of France and Germany, may very possibly offer facilities for the introduction of larger quantities of mineral matter in the pulp. Whilst these practices are allowed to continue so long may we expect to hear complaints of brittleness of structure and bad wearing qualities of the paper.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Artificial Production of Alizarine,
by M. Z. ROUSSIN.

I HAVE already pointed out binitronaphthaline as a fruitful source of coloured products; the action of alkaline reducers, such as sulphides and protosalts of tin, dissolved in caustic potash, cyanide of potassium, &c., yield with this substance very rich red, violet, and blue derivatives. When the reducing agents are acid, as, for instance, when a mixture of zinc and weak sulphuric acid is employed, or iron filings and acetic acid, minute grains of tin and hydrochloric acid, &c., the binitronaphthaline undergoes no alteration. Inquiring into the cause of this unexpected resistance has led me to study more carefully than heretofore the properties of binitronaphthaline. Among these most deserving attention, the following is beyond all others remarkable.

By making concentrated sulphuric acid react on crystallised binitronaphthaline no reaction is produced. When the temperature of the liquid is raised to 250° C, binitronaphthaline dissolves completely, as soon as the liquid becomes amber colour. Only after long boiling will concentrated sulphuric acid begin to react on this substance. Binitronaphthaline is precipitated with its primitive whiteness when these acid solutions are weakened with water. This remarkable stability of an organic molecule in presence of so energetic a reagent as hot concentrated sulphuric acid, calls to mind an analogous reaction. If powdered madder-root is treated by concentrated sulphuric acid at 100° C., all its organic materials are carbonised. Only one among them can resist this violent treatment, and that is the colouring matter of the root itself,—namely alizarine. Now, all chemists know that the formula of the latter substance, as well as its principal properties, denote that probably it belongs to the naphthalic series.

The formula of alizarine is generally represented by $C_{20}H_8O_4$; that of binitronaphthaline by $C_{20}H_8(NO_4)_2$. An opportune reducing agent, which by carrying off two molecules of oxygen and making nitrogen pass to the state of ammonia would probably convert binitronaph-

thaline into alizarine. Experience has confirmed this idea. By the following process artificial alizarine may be prepared:—

Introduce a mixture of binitronaphthaline and concentrated sulphuric acid into a large porcelain capsule, heated in a sand-bath. When the temperature is raised, binitronaphthaline dissolves completely in sulphuric acid. When the mixture reaches 200° C. throw in minute grains of zinc, and in a few instants sulphurous acid is disengaged. The operation takes about half-an-hour. Then if a drop of the acid mixture is made to fall into cold water it develops a beautiful red-violet colour, owing to the formation of alizarine. Sometimes the reaction becomes energetic if a large mass is operated upon, if there is too much zinc, and if the temperature is not carefully attended to. In such a case the sulphuric acid boils rapidly; abundant white vapours are disengaged with extraordinary noise and violence. It must be added that the latter inconvenience is easily avoided by adding only small quantities of granulated zinc, and by watching the temperature. When this accident does happen, the proportion of alizarine is greatly diminished, but still a considerable quantity remains in the residue.

The reaction over, dilute the liquid with eight or ten times its volume of water, and then boil it. In a few minutes throw the liquid on a filter. Cooling causes it to deposit alizarine, in the form of a red jelly, sometimes adhering to the vessels, sometimes suspended in the liquid. In either case this jelly appears, under the microscope, to be composed of a mass of very distinct pointed filiform crystals. The mother-waters are coloured dark red, and hold in solution large quantities of alizarine. They can be immediately used for dyeing after dilution with water and proper saturation. They contain large quantities of sulphate of ammonia. Some undissolved alizarine remains on the filter, which is easily carried off by caustic alkalis or carbonates, and precipitated anew by acids.

In the preceding reaction, zinc can be replaced by various substances; for example, tin, iron, mercury, sulphur, charcoal, &c., &c.,—in a word, by all bodies, simple or compound, organic or inorganic, which react upon and reduce sulphuric acid at a high temperature.

The two following equations describe the reaction:—

In the first equation, it is a metal which reacts on sulphuric acid. In the second, it is the carbon itself.

The alizarine obtained by the preceding process possesses all the characteristics and reactions of ordinary alizarine. Almost insoluble in water, it dissolves in alcohol and ether. It volatilises between 215° and 240°, with a yellow vapour, yielding dark red, crystalline needles; but the colour of these crystals is rather variable. Hydrochloric and concentrated sulphuric acid will not attack it. It dissolves in caustic and carbonated alkalis, with a beautiful deep blue-purple colour; acids precipitate this solution in orange-red flakes. Like madder alizarine, it furnishes most beautifully coloured lakes. Artificial alizarine dyes like natural alizarine, and imparts the same pure tints.

The elementary analysis of madder alizarine has hitherto given variable results. Doubtless, the reason is

the difficulty of freeing the natural product from impurities. The elementary analysis (which I shall make in a few days) of artificial alizarine will definitively establish the formula of this important colouring matter.

M. Dumas, while presenting the preceding paper in the name of its author, remarked, that the identity of alizarine with M. Roussin's artificial product was not thoroughly established. The elementary analysis of the latter has not yet been made. It has not as yet been possible to test certain applications to dyeing and printing processes characteristic of alizarine. It is to be hoped that the Commission nominated will decide the question promptly, the interests at stake being considerable.—*Comptes-Rendus*.

On the Detection of Bisulphide of Carbon in Coal Gas, by Dr. E. HERZOG.

A SOLUTION is prepared by saturating absolute alcohol with ammonia gas. Then a concentrated aqueous solution of acetate of lead is made, and, to insure saturation, a small portion of the solid salt is left in contact. Both these fluids must be preserved in well-stoppered bottles.

The gas to be tested may be conveniently delivered from a length of vulcanised india-rubber tubing, to the end of which is adapted a narrow glass tube, about five or six inches long. Five drops of the sugar of lead solution are then mixed in a test-tube, with about sixty or seventy drops of the alcoholic ammonia. No precipitate will be formed providing the latter solution has not been allowed to absorb any carbonic acid.

The glass tube delivering the supply of coal gas is now immersed in the mixed solution to a depth just sufficient to allow the gas to be forced out by the existing pressure, and to escape in small bubbles. In the event of bisulphide of carbon being present, the liquid becomes gradually coloured, and soon afterwards a yellowish-red precipitate is formed, which, by longer action, assumes a brownish colour. If carbonic acid existed originally in the gas, then a white precipitate is thrown down, which imparts to the yellow-red a somewhat lighter colour.

As a confirmatory experiment, the gas may be first passed through the alcohol ammonia fluid alone and the lead solution subsequently added, when an orange coloured precipitate, appearing either immediately or very shortly afterwards, will be formed if bisulphide of carbon is present. In order to meet the objection that sulphuretted hydrogen may perhaps have occasioned this reaction, let some of the gas be first passed through a small quantity of the simple lead solution. The smallest trace of sulphuretted hydrogen causes a blackening of the liquid, whereas bisulphide of carbon does not alter it in the slightest degree.

It should be mentioned that if the yellow-red precipitate be allowed to remain under the fluid, it gradually changes colour, and becomes white after the lapse of about twenty-four hours. If, however, the precipitate be filtered immediately, slightly washed, and dried, it becomes a dark brown.

With regard to the explanation of the chemical reactions which occur in this process, the interesting observations made by MM. Zeise and Debus may be quoted as proving that, by the action of sulphide of carbon on ammonia, according to the concentration and temperature of the fluids and the proportion borne by the ammonia to the sulphide, so will the relative amounts of the products of decomposition vary. In concentrated solutions, and when ammonia is in excess, sulphocar-

bonate of ammonium and sulphocyanide of ammonium are formed; in dilute fluids and when sulphide of carbon is in excess, xanthionate of ammonia. Therefore, by this experiment one or other product will preponderate according to circumstances, dependent upon the larger or smaller quantity of sulphide of carbon contained in the gas. In any case, compounds of lead are formed corresponding to the ammonia compounds, which possess at first an orange-red and afterwards a golden-yellow colour.

Notwithstanding the complicated nature of the chemical reactions involved in the testing of gas by this process, the author recommends its adoption on account of the practical simplicity which, in his hands, attended the working of a great number of comparative experiments.—*Chemischen Centralblatt*.

TECHNICAL CHEMISTRY.

On the Composition of Cast Iron and Steel, by M. E. FREMY.

(Continued from page 321.)

These bodies were reduced to very fine filings, and this metallic powder freed from all foreign matter was submitted at a red heat to the action of dry hydrogen. In these three trials the filings during the whole of the experiment disengaged considerable quantities of ammonia. This experiment leaves no doubt on the subject, and proves that nitrogen, contrary to the hitherto received opinions, is a constituent of steel. Steel is not then a simple carburet, but a nitro-carburet of iron.

If I be not deceived as to the bearing of my inquiries, it appears to me that they ought to have a certain influence on the metallurgical operations relating to the manufacture of steel. Thus in the cementation of iron, all the conditions appear to be realised which give to the metal not only carbon but also nitrogen. It is probable that the different qualities of steel depend on the duration of the cementation, and also on the relative proportions of the two elements which combine with iron. In the preparation of steel by puddling, it is equally important to determine what are the varieties of iron most likely to yield the proportion of nitrogen required for the constitution of steel; or those which, not containing sufficient, require to have it imparted while being converted into steel.

I have spoken of a steel which has for bases carbon and nitrogen; but this compound is not the only iron alloy, the composition and properties of which are of interest to metallurgical industry. It is probable that bodies bearing some analogy to carbon or nitrogen would serve also in the production of steels. Is it not already known that granulated iron, which is harder than ordinary iron, and which in some respects is allied to steel, is principally obtained by the reduction of minerals containing phosphorus? If the combination of iron with carbon and nitrogen ought to be taken as the type of steel, it would be very curious to determine the modifications undergone by iron when carbon or nitrogen are replaced by other simple bodies. I shall devote another communication to this interesting subject, showing that there are many steels, and that they form a whole group of compounds, each of which ought to be successively examined.

It appears to me that the following conclusions may be drawn from the new facts which I have communicated to the Academy:—

1. In studying the successive or simultaneous action of nitrogen and carbon on iron, ammonia may be used advantageously to furnish nitrogen, and lighting-gas carbon; the chemical reactions thus produced by gases, yield pure compounds; they can be easily observed and regulated.

2. When iron has been submitted, not for too long a time, to the action of ammoniacal gas, it produces no crust of nitride of iron, it is simply nitrogenised, becomes then of a zinc white, partly preserving its malleability, and resembling a real alloy.

3. Iron heated in a current of lighting-gas immediately becomes carburetted and transformed into a very soft, grey graphite like, fusible cast-iron, which is suitable for the finest castings. Steel is never formed in this reaction of lighting-gas on cast-iron.

4. Steel is formed by the reaction of carbon and nitrogen on iron.

5. Pure iron, which, under the influence of lighting-gas, is transformed into very fusible cast-iron, is previously nitrogenised, loses its fusibility, and is converted into steel by the action of the gas. Fragments of the same metal have been nitrogenised for different lengths of time, and then submitted to the action of lighting-gas; those retaining a small proportion of nitrogen were very incompletely converted into steel; those, on the contrary, which were strongly nitrogenised formed a beautiful steel. It is, then, in some measure, the quantity of nitrogen contained by iron during carburisation which determines the degree of acieration.

6. It does not seem to me possible to admit that cementation may be produced exclusively by a carburetted volatile body, since lighting-gas acting at red heat on iron forms only cast-iron, while by the previous presence of nitrogen in the metal it is immediately converted into steel.

7. When iron is transformed into steel the nitrogen is not eliminated by carbon, for I have ascertained that all the steels of commerce are nitrogenised, and disengage an abundance of ammonia when submitted to the action of dry hydrogen.

8. All these facts tend to the following conclusion, which is a condensation of my paper:—That steel is not, as it has hitherto been considered, a carburet of iron, but rather a nitro-carburetted iron. I have adopted the title of nitro-carburetted iron to explain the composition of steel because it well expresses my opinion of the composition of this body, in which such small proportions of metalloids so completely modify the properties of iron.

The paper having been read,

M. DUMAS rose and congratulated M. Fremy and the Academy on the important results which must flow from the labours of the author of the paper. The theory of the production of steel seemed henceforth determined, and it might reasonably be hoped that great practical results would ensue. Who, for instance, did not foresee—and it was for M. Fremy to follow out the demonstration—that great advantage would result from these new, methodical, regular, and certain processes, when there was occasion either to case-harden the surface or edge of certain iron implements or instruments? After having forged, filed, and finished them off in the state of iron, a current of ammoniacal and carburetted gases would convert them more or less completely into steel. The depth of the stratum of steel being regulated by the duration of this gaseous cementation with a certainty never obtainable by cementation with powders, or by the use of horn or animal matters in the empirical pro-

cesses. The Academy could but congratulate M. Fremy on his present success, and on his disinterestedness in publishing his important labours.

M. MORIN remarked that M. Fremy's researches explained numerous empirical receipts and processes for the cementation of steel. In most of these processes mixtures were employed containing various proportions of carbon, and of more or less nitrogenised substances, such as ammoniacal salts, horn shavings, leather cuttings, soot, &c., &c., the result being a cementation more or less deep according to the use to which the instruments are to be applied. He thought it necessary also to observe that the character of steels produced by different methods varied greatly, not only where these methods differed, but also with almost identical processes. Moreover, certain kinds of steel, and it seems particularly those obtained by puddling, after undergoing many energetic fagottings, appear to be susceptible of losing their characteristic properties of hardness and elasticity acquired by tempering, and to acquire a considerable resemblance to the most ductile irons. Lastly, the cast steels produced by the new processes of fabrication, when properly forged, possessed an elastic resistance, capable of undergoing a much greater strain than those manufactured by the ordinary methods.

Besides the foregoing speakers, several members of the Academy joined in the discussion when M. Fremy's paper had been read, and among other remarks it was stated that the composition of cast iron might be different to that of steel. M. Chevreul then made two observations, one respecting black cast iron, and the other on the composition of steels.

1. **On Black Cast Iron.**—At the end of the last century (1799) Proust observed that when treated with weak sulphuric acid, black cast iron yielded an oily matter, a portion of which was carried off by the hydrogen gas and made the tubes of the apparatus greasy, while the other portion remained mixed with the black residue, from which alcohol could extract it. I never neglect an opportunity of quoting this observation of my illustrious fellow citizen, as an example of the possibility of producing, by chemical forces, compounds analogous to those of organic nature. Experience has long since proved that aqueous vapour by reacting on charcoal, yields, besides carbonic acid, or oxide of carbon, nothing but hydrogen, and not carburetted hydrogen, as hitherto believed:¹ the combination of the cast steel with the nascent hydrogen seeming to me difficult to admit; this has led me to conjecture that in Proust's experiment the water might assist in the production of the oily matter simultaneously with the carbon and hydrogen. Now, M. Fremy's observations seem to throw a light on the subject, by indicating that it is not carbon, as was represented, which yields the oily matter.

2. **Composition of Steels.**—Independently altogether of science, two bodies possessing different properties have never been confounded; so that when an iron was observed which hardened on being suddenly cooled, it was distinguished from one preserving its original ductility after undergoing the same cooling influence. Thenceforward the name of steel was bestowed upon the first substance to distinguish it from what is properly called iron, or, in other words, between steel, which tempering hardens, and iron, which tempering does not harden. Since the time of the revival of chemistry the difference between steel and iron was attributed to the presence of about a thousandth part of carbon in the

former. Later, the influence of various bodies on steel was recognised. Berthier mentions chromium; Faraday and Stodart aluminium, platinum, and its accompanying metals; but the fact which to me seems of the greatest importance, is the method by which MM. Faraday and Stodart obtained from cast iron some centièmes of iridium and osmium, which when analysed yielded no trace of carbon. Setting aside the question whether steel is an indefinite compound of iron and one or several simple bodies distributed through the whole mass of the steel, or whether it is a definite compound of iron with one or several simple bodies distributed in indefinite proportions in the iron in excess of the elements of the definite compound, I conclude, from the whole of the facts I have stated, that in a chemical treatise steel in general must be regarded not as a definite compound by the nature of its constituent parts, but as a particular state of iron produced by the union of this metal with bodies the nature of which is variable, and it is from this point of view that, after defining steel, independently of all scientific considerations, as an iron which is hardened by tempering, I discriminate in my fourteenth lesson on "Chemistry applied to Dyeing," published in 1829, p. 78:—

1. Steels formed by iron and carbon;
2. Steels formed by iron, carbon, and a third body;
3. Steels formed by iron and some other body which is not carbon; or uncarbonised steels.

The results of M. Fremy's interesting experiments are, it seems to me, easily connected with what is already known of steel if looked upon from the point of view I have explained, instead of regarding them in the general way. It is now important to find out,—1, Whether it is true, as Guyton says, that diamond dust will turn iron into steel; 2, Whether acieration can be effected without the intervention of nitrogen.

M. FREMY said, in reply to the preceding observations, he was happy to observe the interest the Academy took in his enquiries on steel, and he thanked its members for the friendly way they had spoken of his labours. It was not his intention to treat, in the present communication, of the influence exercised by nitrogen and carbon on the properties of iron, but all questions relating to the fabrication of steel and cast iron had for a long time been carefully studied in his laboratory, and the results would by-and-by yield materials for papers bearing on the following points:—

1. The relative proportions of nitrogen and carbon required to be introduced into iron to form good steel;
2. Circumstances opposing acieration or altering the qualities of a steel when formed;
3. The mode in which carbon penetrates the metallic mass;
4. The reason why such small quantities of carbon and nitrogen can convert iron into steel;
5. The study of steels containing metals such as manganese, chromium, tungsten, aluminium, &c.;
6. Classification of different kinds of cast iron; examination of the effect which silicium, phosphorus, arsenic, and sulphur exert upon these compounds; study of the cast iron best suited to the fabrication of puddled steel.

—*Comptes-Rendus.*

Griffin's Reverberatory Gas Furnace, for Analytical Operations with Platinum Crucibles.

THIS apparatus produces a high temperature without the use of a blowing-machine. It is especially suitable for the decomposition of siliceous minerals by fusion with

¹ "Eighth Lesson on Chemistry Applied to Dyeing," pp. 23, 24.

alkaline carbonates in platinum crucibles, being capable of fusing 1000 grains of anhydrous carbonate of soda in ten minutes.

The furnace is represented by the annexed engraving.

It consists essentially in a combination of tubes, within which a mixture of coal-gas and air is burnt, and in which a small fire-clay or plumbago furnace holds the crucible in the point of greatest heat.

Letter *a* represents a brass tube and stop-cock of $\frac{1}{2}$ inch bore, for the supply of coal-gas at ordinary pressure. The end of it, fixed within the tube *b*, is pierced with several small holes for the emission of the gas. The brass tube *b* is 9 inches long and $\frac{1}{2}$ inch bore, open at both ends. The iron tube *c* is 8 inches long and $2\frac{1}{2}$ inches diameter, open at both ends, but joined at the top to the iron body of the furnace *d*. This body is 4 inches high, and 4 inches in external diameter. The iron tube *e*, made conical at the lower end, is 15 inches long, $2\frac{1}{2}$ inches wide at the top, and $3\frac{1}{2}$ inches wide at the bottom. The body of the furnace, *d*, is fitted with a lining of fire-clay or plumbago, the upper part of which is cylindrical, with a bore of $2\frac{1}{2}$ inches, and the lower part forms a massive diaphragm, with a central opening of $1\frac{1}{2}$ inches, as shown by *f* in the section. Upon this diaphragm is loosely placed a cast-iron ring with three knife-edges, represented in the section and separately by the figures *h* and *i*, the use of which is to support crucibles. By reversing this ring it can be made to suit crucibles of different sizes. In the lower part of the chimney, *e*, a reverberatory dome of fire-clay or of plumbago is fed. This serves to deflect the flame downwards upon the top of the crucibles. The space provided in the body of the furnace for the reception of crucibles is $2\frac{1}{2}$ inches wide and $2\frac{1}{2}$ inches high, and it will take in a crucible of nearly those dimensions.

The furnace is supported by a flanged iron ring, *h*, attached to a triangular socket, which can be screwed on the $\frac{3}{4}$ inch rod of an ordinary iron retort-stand, as represented by *n*, *o*.

The gas, entering the furnace by the supply-pipe, *a*, mixes with the air, which rises through the lower end of the tube *b*, and burns with a smokeless flame when lighted at the upper end of that tube. This flame is then supplied with additional air by the lower end of the tube *c*, a great draught being produced by the action of the tall and wide chimney, *e*. When the pressure of the gas is strong, the flame reaches from the tube *b* to the top of the chimney *e*, being in that case two feet long. The point of greatest heat is at 8 or 9 inches above the upper end of the tube *b*, and the arrangement of the furnace is such as to fix the crucible in the focus of the heat. The condition of the crucible can at any time be seen on lifting the dome and chimney *e*, by means of the handles *l*, *l*.

The amount of gas supplied to the furnace is regulated by the stop-cock *a*, from which a flexible pipe should lead to a second stop-cock, attached to a fixed gas-pipe. The latter should be opened wider than is necessary to supply the furnace with gas. The pressure should then be regulated by the stop-cock *a*. This arrangement prevents, to some extent, the blowing down of the flame when the pressure of the gas in the pipe beyond the fixed stop-cock happens to be suddenly lessened.—*Pharmaceutical Journal*.

PHARMACY, TOXICOLOGY, &c.

Improvements in the Processes for the Preparation of Hydriodate of Ammonia and Veratria,¹ by MURRAY THOMSON, M.D., F.C.S., Lecturer on Chemistry, Edinburgh.

Hydriodate of Ammonia.—There are at present two methods in use for the preparation of this salt. One of these is the same as that given in the Edinburgh Pharmacopœia for the preparation of iodide of potassium, only that the iodide of iron, which is first made, is decomposed by ammonia or carbonate of ammonia, instead of by carbonate of potass. By separating with a filter the insoluble oxide or carbonate of iron, the hydriodate of ammonia is obtained in solution, which it is now only necessary to evaporate, at not too high a temperature, so as to obtain the salt. The other method is to make first a solution of hydriodic acid, by passing sulphuretted hydrogen gas into iodine suspended in water. Hydriodic acid is thus formed, and sulphur precipitated; the latter is separated by filtration, and the acid filtrate is neutralised with ammonia or carbonate of ammonia, and then evaporated to dryness as before.

In either of these ways the salt may be made quite pure, at least so far as obtaining a solution of it is concerned. It is in the evaporation of this, so as to get the dry salt, that the difficulty lies in obtaining it quite colourless. Almost invariably, as the drying of the salt is just being finished, a slight decomposition takes place, and some of the iodine is set free, and communicates its brown colour to the whole mass. To obviate this tendency to decomposition is the purpose of my improvement, and it consists, in the first place, in taking care that the salt, during the time of its being dried, shall always contain a slight excess of ammonia; and, secondly, in reconverting the liberated iodine into hydriodic acid, by from time to time allowing a small amount of sulphuretted hydrogen gas to flow over the salt while it is being dried, an apparatus to evolve the gas being kept

¹ Read before the Pharmaceutical Society of Edinburgh.

at hand during the operation. The effect of adding the gas is, that the brown salt almost immediately becomes white. As soon as this bleaching, so to speak, is effected, the stream of gas is withdrawn, and the drying continued, and only resumed if iodine should be liberated a second time. If the salt is well prepared at first, it seldom needs the second application. As soon as the salt is dry, it should, while warm, be put into a dry stoppered bottle, as it is deliquescent. As long as the salt is dry, it will keep a long time colourless, but if it get damp, it is partially decomposed and again gets brown, but its colourless condition may again be restored by a repetition of the above treatment.

It must be admitted that an infinitesimal amount of sulphur finds its way in among the salt, by the use of the sulphuretted hydrogen gas as a decoloriser; in fact, whatever quantity of that gas is actually consumed, has its sulphur precipitated into the hydriodate. To show, however, that this is really no drawback to the use of the gas, I may mention that an exceedingly small amount of free iodine is enough to communicate a considerable depth of colour to a comparatively large amount of the hydriodate. Now, it is to yield hydrogen to this iodine that the sulphuretted hydrogen gas is employed. The greater part of the gas is, however, dissipated as such, and the quantity of sulphur, therefore, is necessarily small in quantity: in fact, it is so minute that I have not been able to detect its presence in the samples I have prepared by this process, although I employed our most delicate tests for sulphur. I beg, therefore, to recommend the above process for adoption in the preparation of hydriodate of ammonia, a salt which most will agree is far from being easily obtained in a colourless condition.

Preparation of Veratria.—In all the processes as yet published for the extraction of veratria from the cevadilla seeds, which contain it in largest amount, as those given by the London and Edinburgh Pharmacopœias, as also the one given by Wittstein (*Repertoire für die Pharmacie*), alcohol is the agent employed in the very first treatment of the seeds, so as to dissolve out the alkaloid.

I propose to substitute for the use of spirit at this stage that of boiling water acidulated with hydrochloric acid, proceeding as follows:—The cevadilla seeds are denuded of their capsules by the method recommended in the Edinburgh Pharmacopœia. Any convenient quantity of them is covered with the boiling acidulated water, which is allowed to act on the seeds for twenty-four hours. The liquor is then strained and poured out, and the residual seeds again treated with hot acidulated water as before, such treatment being repeated six or eight times. The accumulated liquors from these operations are now evaporated to about one-twentieth of their total bulk. Ammonia is now added until no more precipitate is thrown down. This precipitate of impure veratria is now separated by a filter, washed, and then dried on the water-bath. It is now reduced to powder and treated several times with hot alcohol, which will dissolve out the veratria and very little else. The use of alcohol here is not, however, essential, as the alkaloid might again be extracted by acidulated water; but on the whole it seems better to use spirit at this stage, as the veratria dissolves out comparatively free from impurities. It should also be remembered that the quantity of spirit needed to dissolve out all the veratria contained in this precipitate is far less than what would be needed to extract the same from the mass of seeds it

corresponds to. The amount of alcohol used in the latter case is nearly six times that of the former.

After the spirit has dissolved out the whole of the veratria, the solution is distilled, by which much of the spirit is recovered. The half-aqueous half-spirituous residue is now evaporated, so as to expel all the spirit. Acidulated water and a moderate quantity of animal charcoal are now added, and the whole is heated and filtered. More acidulated water is added to the residue, the heating and filtering being again repeated. This should be done five or six times,—as long, in fact, as the filtrate will yield a precipitate by ammonia. Ammonia is now added to the collected filtrates, when the veratria is thrown down. It is now separated and dried. As so obtained, it has a pale straw colour. It will be obtained whiter by repeating the treatment with the acidulated water and charcoal.

By this process I have obtained at the rate of twenty grains of the alkaloid from one (avoirdupois) pound of seeds. In one or two more trials of this process, I have no doubt this amount might be somewhat increased.

I may make the following addendum on the subject of veratria, having reference to a test for it. In most chemical manuals which treat of this alkaloid, it is said that it gives with nitric acid a red or crimson colour, and with oil of vitriol also a red, which afterwards becomes yellow. In any of the samples I have either made or seen, I have not been able to get any colour at all with nitric acid, and with sulphuric acid the following is what I have observed:—When the veratria and the acid are mixed, no colour at all, or a very feeble one, is at first developed; but in the course of three or four minutes a full blood-red colour is given, and this may last for two or three hours quite unchanged, after which it gradually fades away. The only other substance which is likely to be mistaken for it is, therefore, salicine, but the points of distinction are these: with salicine, the colour given by sulphuric acid is immediate, and is not blood-red, but decidedly purple-red; and then the colour is so permanent as to last over six hours, by which time the colour of the veratria is quite gone.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, May 3, 1861.

On the Solar Eclipse of July 18, 1860, by MICHAEL FARADAY, D.C.L., F.R.S., Fullerian Professor of Chemistry, R.I., Foreign Associate of the Academy of Sciences, Paris, &c.

I do not wonder at your desire to be here this evening. We had the hopes of an account of the eclipse of last July from one who was the directing spirit of the investigations then made, and with every intent and desire to give us that account here, the very matter respecting the eclipse has so accumulated upon him as to prevent that taking place; and we cannot possibly be so unjust as to urge a compliance with an assent made at a distant time, when he thought he could accomplish what we desired, since he is now preparing results, and doing far higher service to science than he would be doing even here, where the purpose is to convey to your minds matter which I may, perhaps, be able, certainly not so well, but perhaps with sufficient clearness, to lay before you. Mr. De la Rue was the person who guided the expedition, of which I am to be the mere mechanical agent in giving you an account.

There happened an eclipse in the month of July last

year. You know very well that the three great bodies—the sun, our earth, and the moon, are rolling amongst each other; that, whereas the moon must ever cast a shadow as well as the earth, the sun being the source of light, those shadows travelling through space must be always cast somewhere, except when they coincide. When the shadows of the sun and moon coincide, we being outward from the sun, we have an eclipse of the sun; when otherwise, we have an eclipse of the moon. And it so happens that the eclipse of the 18th of July last year was a most remarkably fortunate one for the observers of Europe. It was visible on a part of the earth accessible to us, namely, Spain and part of Algeria, and at a time when the moon was nearest to us, and the sun furthest from us; and it so happened that the projected discs of those two bodies in the heavens were in that position in which the image of the moon overlapped and surpassed that of the sun; and, therefore, to those who took the centre of the line described by their shadows there was, in fact, a total eclipse of the sun. And not merely was there a total eclipse of the sun, but that total eclipse would last for the longest time that could very well happen in the juxtaposition of the three bodies—namely, for three minutes and a-half. The eclipse began in North America, came across the Atlantic, passed over Spain, crossed the Mediterranean into Algeria, through the northern parts of Africa, and terminated, as far as the records reach, just about the Red Sea. We have here maps showing the path of the eclipse in Spain, and in the centre of that path, for nearly sixty miles' width, so much of the sun was covered by the moon as to make the passage of the moon in that part occupy about three and a-half minutes—the partial eclipse, of course, lasting much longer.

Now, you will understand that since the time of Herschell the elder, men have thought much more philosophically about the condition of the sun and moon than they did in former times. He first gave us views respecting the constitution of the sun, gathered partly from the spots and holes occurring upon its surface, which at first almost alarmed and startled the philosophers, but which have been, as it were, only the first sowing of seeds of knowledge to produce fruit hereafter. This knowledge has been growing from year to year, from eclipse to eclipse, in a most extraordinary manner. Every effort is being made to take advantage of these rare opportunities for observing the sun physically and philosophically; for you may get a peep at the sun at these times which you can never get at any other. To observe the moon blotting out the sun from observation, and yet letting you close by the sun, so as to see the stars and planets which would be always visible in the day time, but for that wonderful flood of light which puts all others into the shade,—to get such an opportunity is most important to the philosopher, especially since the occasions are so rare that for a man who has seen one to have witnessed another, and so been able to add the experience of the first to his judgment in regard to the second, is a remarkable occurrence. That man, Airey, whom I like best to designate by his name which is his highest honour, has seen no less than three solar eclipses, and has stored up so much information and judgment respecting them as to make him the chief of the party who went forth to observe the recent phenomena. I believe philosophers in all countries send their reports to him, and they go forth to the world hereafter in a proper manner, about which as I have said, he is now engaged.

Now, what is the sun? Is it a great fire? No. Is it an electric spark? No. There are plenty of reasons for saying that the sun is not that. It is possible to raise a conjecture in the mind of the philosopher which shall give him a reasonable hope of ascertaining the nature of the sun. The more, however, we can see of the sun, the better we shall be able to judge of it. Not the more brightly we see the sun, but the more closely and distinctly; and the great use of the late expedition to Spain

has been in its giving us a great deal more of that knowledge. What is the sun, then? I can show you a little sun here in the voltaic light. It is a brilliant spark, and what would it be to look at the edge of that light, to examine the condition of that part between it and darkness? You tell me, and you say truly, that if you look at the sun you cannot tell what is its form and condition; it is too brilliant and beautiful—"dark with excess of light."

An eclipse is the only opportunity we have of seeing anything like what belongs to the sun,—essentially belongs to him, and keeps him in that condition which makes him essential to the whole world, to the worlds of worlds, to all the stars and planets that pass through space,—that condition which makes an essential part of his constitution, which belongs to his physical history even more than the light that shines upon us. The light has shone upon us so long, it shines upon us day by day, hour by hour, minute by minute; we could not live without it; neither plants nor animals could grow without it; we have it so constantly with us that it is regarded as one of the commonest things in the world. So we think of the sun; but to get at the truth of the matter with regard to its physical condition, we must also know that which belongs to its outside, I was going to say; we do not know how it is finished off in space; is it a hot body sustained by any action going on from day to day? What evidence have we? We must look at that when the eclipse comes on, when the sun is hidden—not by your hands, as in the case of our bright light here, but by the moon, which blots it out entirely;—then is the time for our examination, for if the least part of the light is present you have no chance of seeing anything beyond the light of the sun. The smallest particle of sunlight is far brighter than our voltaic light, and prevents your seeing anything else. It does happen now and then—it won't happen for many years to come again—that you have a complete occultation. Now, think of the philosophic spirit exhibited on the last occasion, in July. There was to be a hiding of the sun for three minutes; it was to take place in a distant country; it would be an expensive undertaking to get there, up in the mountains, or the plains; and there were the chances of the weather against any observations being made—let but a cloud come over the place for three minutes and a-half, and all the exertion would be lost;—yet men were found ready to go. Fifty philosophers started from Great Britain, and Government placed a fine ship at their disposal. Many of them left the Association at Oxford, which was then sitting, to go out to the mountains and plains, and make their observations. Fortunately, they had fair weather, and they went and succeeded. I am ashamed to say that I do not remember the names of many of those who so richly deserve our thanks for their efforts. Amongst them, however, a certain party was organised to observe the sun photographically. Perhaps you wonder that we should make any point of that. You know the wonders of photography—how it not only enables the sun to give us his own picture, but enables him to give us the pictures of other persons who are lighted up by his rays. Now, of what service is this in the case of an eclipse of the sun? Why, it can do wonders. We have tried, and we therefore know, what can be done. You look at the eclipse; you see the disc of the moon gradually advancing till the sun is perfectly obscured, and you find it is hidden for three minutes. It is only during those three minutes that you can see what you want—that interval between light and darkness which belongs to the outside of the photosphere of the sun,—and where is the mind that can remain steady enough, during that brief interval, to devote all its energies to the use of the means provided for recording the phenomena, and not be led away by those momentary splendours which, perhaps, will never be witnessed again? Who, among all those who went to Spain last July, will ever see another eclipse? I am told by astronomers—I know

nothing of the subject myself—that the occurrence will not happen again during an ordinary life. What we want, then, is an eye that, in looking at the sun, shall not be blinded, as we are here in looking at our voltaic light. Providence has given to the eye such a wonderful power of adaptation, that if I look at this light for a time, the eye is so changed as to be incapable, for a moment or two, of ordinary vision. Now we want an accurate eye—which photography gives us—that can receive and record an impression of the condition of the sun when it is just hidden, or of those parts which are visible,—an eye that can see and record these things, not misled by the previous brilliancy. For this is the beauty of photography: it can record what has happened, so that it can be examined afterwards. What are mind and memory in man when disturbed by these extraordinary appearances of a solar eclipse? Some of those zealous observers who went to Spain last year told me that there was not one of them who kept possession of his mind so thoroughly as not to be a little misled this way or that way by the wonders of the phenomena they witnessed; and he to whom I now principally allude, because his investigations most concern me, at one moment almost regretted that he had taken charge of the expedition under his care (which cost him personally 300*l.* or 400*l.*, and required a large staff and a great deal of apparatus) because it deprived him of the pleasure of looking about and seeing the glorious sight comparatively undisturbed. I dare say that many of those who merely looked on were more happy in gazing at the beauties of the eclipse and the wonders of the landscape, than those who were engaged in special investigations which they had to record. You have, then, in photography an eye which can look at the sun, and which, looking there for a few seconds, can take upon its memory—that is its collodion—a perfect record of the sun's appearance, and keep it for ever; then, by means of successive plates, you have an eye which can take another look, and then another, and perhaps another, if the weather be propitious, and bring away all these impressions faithfully recorded for future observation. Now, I must try to impress you, if I can, with the real duty performed by this body of men to whom I have alluded. Mr. De la Rue went out with five assistants—Mr. Beckley, Mr. Downes, Mr. Beck, Mr. Reynolds, and Mr. Clark, all of whom were perfectly well educated in regard to the operations with which they were entrusted. They were determined not to fail when the eventful three minutes came which would never return; and so well did they carry on their operations, under the generalship of their head, that they brought away not fewer than thirty-three photographs of the sun during the eclipse, four of them taken just about the period of totality. They narrowly escaped being burned up, for the corn around them once took fire; and they had also the chance of an accident from the wind, which blew very roughly; but they succeeded in those three minutes of utmost excitement, and procured those photographs of the sun which I am now about to show you. I have no time to tell you what the Government did in lending that fine ship, the *Himalaya*, for the occasion; what the Spanish authorities did; what Mr. Vignolles, the engineer of the railway, did; and, indeed, what they all did;—I will not take up your time in returning thanks to those who have worked so well for science. You may say, it was, no doubt, an easy thing for the sun to represent his own face in a photograph, since he can give us the faces of others; but there is this peculiarity about the sun, that over action destroys everything. You see here a representation of the sun with certain dark spots, which can be very well obtained by using the proper means; but leave the picture a little too long, and out go the spots; the matter is over-acted upon, all peculiarity disappears, and nothing but a dull appearance remains behind. It required a special instrument, a remarkably beautiful instrument, which has been constructed for some

years, and placed at Kew, called the photoheliograph. This was placed in Mr. De la Rue's hands, with a sum of money by no means sufficient for the purpose, to enable him to carry out his operations. The first view I shall show you will be a picture of these men themselves in a group. You will imagine that they have left England and arrived in Spain, landed at Bilboa, and gone over the mountains. Mr. Vignolles has conveyed two tons of apparatus to the spot, and they are all now upon the ground. You see the photographic house, and the instrument, which is like a mis-shapen telescope pointing up to the sky, being balanced upon its axis by a weight with a proper clock-work arrangement. As soon as the sun's rays enter the instrument, they pass through the glasses which the optician puts there, and are afterwards expanded by means of other arrangements until they fall upon a collodion plate below, of $4\frac{1}{2}$ inches diameter. Upon that the sun has to make its own face; but let the sun look there but a moment, whilst you count one, and the face is spoiled. In order to get a proper impression, you require a time so short as scarcely to be measured except by micro-metrical means. The only way was to take a certain opaque screen, and cut a small slit in it, and then, by a proper arrangement, to draw the slit as fast as possible across the bundle of rays passing at that spot; and that—I do not say second, but that instant, was sufficient to secure a full and perfect impression. This is the way in which pictures are taken by the photoheliograph. You have now a view of the *Himalaya* on its voyage outward, for you are fairly entitled to see how they proceeded from the commencement. Another view gives you a representation of one of the waggons in which luggage had to be carried over the country. Mr. De la Rue has set himself down upon a threshing floor,—a hard place where the corn is spread out, and the oxen wander to and fro treading it under their feet. You see also the chamber which had to be taken out and built. Here also is the telescope and the apparatus. Mr. De la Rue will now give us a view of the sun itself, with one of its spots. A second view shows us the same spot but in a different position, owing to the revolution that has taken place. In this way we are able to compare the history of these spots from time to time.

A few views will now show us the progress of the eclipse. The first shows the sun to be partially obscured, but the spots are visible. The next shows the moon's disc advancing. And the third exhibits an almost total obscuration, leaving only a crescent of light. The next view is taken at the period of totality, when there is an entire extinction of the sun by the moon. And now you see all these beautiful phenomena, these luminous appearances which have been so accurately photographed. You must not suppose that all these pictures precisely correspond in luminosity to the brilliancy of the objects represented. Though the negative may give an exact representation, the different impressions from the same negative will vary, and present some irregularities owing to the peculiar state of the atmosphere at the time. Clouds, dew, rain, all these different phenomena operate as a disturbing influence, and hence the irregularities in some of the impressions. However, we are obliged to compound for many things, and accept them as we can get them. But vain are all regrets. The services rendered by photography are still remarkable. I do not ask Mr. De la Rue what he remembers, what he observed, of the eclipse; I ask him what he has recorded and brought away. Two of us may differ in opinion as to what took place, but there is the fact, the record made at the time, to appeal to—the enduring representation of the exact state of the sun at that time. While Mr. De la Rue was directing the photographic operations, attending to the time, giving as much as a minute to the first photograph and about twenty seconds for the second one, he was looking through his telescope at the sun, either with or without shade, as the eclipse advanced, and making

drawings by hand. I have some of them here, and they tally perfectly with the images and representations given by the photographs. In order to give you an idea of what was seen around the sun during the eclipse, I must refer you to our diagrams. There you perceive what are called red prominences—one never does get good names for these things—certain red appearances not of an ordinary kind, which are seen upon the sun when it is blotted out by the moon. You see them in different positions according as the moon advances. You observe one prominence, or rather independent existence, floating above the sun, touching neither the sun nor moon. You would wonder if I could tell you how these things have been recorded—these great prominences about the body of the sun. Here is one 28,000 miles in length. Now we know that the body of the sun is exceedingly light, far lighter than the matter of the earth. What, then, can this be which is floating above it, a cloud in the air, with the most luminous part towards the sun, whilst the other bodies had their luminous parts away from the sun? That one prominence is, I think, 28,000 miles in length—for these things can be measured and have been measured—and 74,000 miles above the sun. Now what is 74,000 miles? It is three times the circumference of the earth. Such is the height of that cloud, as far as we know it. It may be much farther in physical existence for what we can tell. Perhaps we may know hereafter. At present we are only taking the first steps. We are infants learning to walk with regard to this part of the sun. No one can imagine that what we are doing here is anything else than what will appear as absurd speculations and crude conjectures when we make further discoveries in the mode of observing these things. There has been no eclipse in which the mode of observation has not advanced on that of its predecessor in the most wonderful manner, and we shall still go on advancing. We now give you views of the eclipse in its various stages; and here we have a view of that beautiful appearance the corona, which I knew would call forth your admiration. This differs in character at different times, sometimes appearing like superposed discs, and at other times having this glorious stellar character streaming out behind the moon, the moon appearing like a brazen globe before it. This is not a photographic corona which you have before you, but it is an accurate drawing brought away from the spot.

The most important question to be solved by these observations was, what are these prominences? And the first part of that question is, what do they belong to? Are they solar? Or are they lunar? Or do they depend upon the sun, moon, and earth? Where do they exist, and what are they? One of the chief results, perhaps, of Mr. Downes's observations is, that they belong to the sun. Consider what is taking place. There is the disc of the moon moving over the disc of the sun, and it is looked at by persons who choose a position where they may get into the centre line of the projection. Amongst other prominences there was one, here represented in the diagram, which, I believe, appeared before the sun was entirely out of sight. Mr. Airey and several others saw it before the sun was completely obscured. Now, that is not a prominence which is first of all brought into sight by the shading away of the sun, and then cut off from the sight by the moon sliding over it; but it is a prominence which, when it comes into sight, goes sailing along upon the edge of the moon, and may remain in sight some time. There is another of the same kind, projecting above the moon at every part, and not disappearing at all from us by any occultation—only disappearing when the brilliant light of the sun, arising from the uncovering of his face, comes into view and extinguishes all other things. But then there is this other question—what do these prominences tell with regard to their place upon the sun or the moon? One or the other or both? What is their story? Their story, as I understand it, is that they are

upon the sun, and for this simple reason. Very great care was taken by the astronomers to measure off the places of these appearances; they are all marked off in a beautiful manner, so that they can identify the different prominences when they see each others drawings, whether they stand in the line of the eclipse accurately, or a little to the right or the left—they all correspond in the position of the prominences. The sun, then, being put into the telescope, and motion given to it, so that it remains fixed in the telescope, the moon appears to pass over the sun in a given direction, and while it covers up some prominences it uncovers others, and slides between others; so that they would appear to belong to the sun and not to the moon. That is a question which seems to be entirely solved by these observations. Here is a prominence in the diagram; if it belonged to the moon, it would have moved with the moon; but belonging to the sun, it is left behind. A careful comparison of the centre of the moon and the centre of the sun, with the places where these prominences appeared, declares that they belong to the sun. That is a most essential and important point to have ascertained with certainty. No sound philosopher can run away and say that these things belong to one body when they belong to another. The great thing is to proceed cautiously, and draw our conclusions with care, lest we slip and fall. We must go on step by step, and be certain as we proceed. I have said that some of these objects are 74,000 miles distant from the sun. One or two of them appear like detached clouds, the time is too short to observe any change in their shape, but they are of different shapes and appearances in different eclipses. Of course you do not suppose that the profile of the sun directed towards us at the time of the eclipse is the only one that has these protuberances upon it. Surely the sun revolves, as the spots prove to us, and if another profile was presented to us we should have other prominences. We cannot doubt that these things which we see exist all over the face of the sun. We know that the moon is a round body because every profile she gives us is round. So it is with the sun; whatever profile we have, these prominences come into view, and we may therefore conclude that they exist all over the surface. It is a remarkable circumstance that a few days after the protuberances were seen there came into view a set of spots upon the face of the sun which corresponded in position according to the revolution of the sun, with the places where the prominences were observed during the eclipse. That is a suggestion that one catches hold of, with a view of verifying at a future time, and putting upon record with the other data which are given.

Another question has been whether the light that came from these prominences or from the corona was polarised. Now it is not my intention to take you into the question of the polarisation of light, but it is an important indication of the probable nature of these substances if the light from the corona or the protuberances is found to be polarised. The light which comes direct from the sun is not polarized, but that which is reflected is polarized; therefore there is an indication of something that sends that light to us in a modified form. Many questions of that sort will come before us in due form as the investigations proceed. Then with regard to its actinic character. We have before us the voltaic light, and we have so arranged it that it shall come through the lens, then through the prism, and then go away to the screen, and there you will see it, decomposed, according to Newton's discovery, into what he called the spectrum—that is, the rays separated. These rays have different powers, and here you begin to see some of the wonderful circumstances connected with the eclipse. You see that the different rays have different characters by their various colours on the screen. These rays write photographically upon proper media (we are now dealing photographically with the sun), and they write not in proportion to their brightness as we see them, not as they write upon the nerve of the human eye. And here comes

a most important part of the philosophy of this subject. You see on the screen how far the rays are visible to you; but then we know that, chemically speaking and photographically speaking, beyond what you can see there are rays which are far more important to us, in many respects, than those which are apparent to the eye. To show this Mr. Downes will take a photographic view of the ray of light which you see going on to the screen, by intercepting it with a prepared plate. As soon as the plate is put in you see how far the rays are visible—the red, green, violet, &c., as you saw them on the screen, and we will mark the limits to which they visibly extend. If those were all the rays, you would of course find that the picture produced on the plate, when developed, would be limited to that space. Now the picture has been developed, and you observe that it extends beyond the limits of what was previously visible, and the outer rays have told chiefly in the production of the picture. They write their image far more beautifully by photography than they do upon the eye itself. These outer rays which have formed the darker part of the picture, where on the screen we could see nothing, are those magnificent and wonderful rays which make plants grow green, and make animals thrive and become cheerful. We have here a picture marked at the places where the red, and the green, and the blue rays fell, and you see these are not the places that exhibit the actinic power. In fact, the red ray has made no impression; the green has made but little; it is at the outer part, beyond the blue, where the most abundant indication of these beautiful actinic rays is apparent. We should make no advance unless we had men to make these observations, to think about them, and consent to have no answer to give to many questions which you may put to them.

My remarks may have suggested a score or a hundred questions to your minds—what is this? and what is that? Well, we must be content to confess our ignorance; we must be satisfied with getting only one point in advance, which will be a point of attachment for further progress. I had intended to say something about the spots in the sun, but our time is nearly expired. We have several drawings here showing a certain condition of the sun, which is only visible now and then, and which appears differently to different eyes. According to Mr. Nasmyth the whole photosphere of the sun is covered with images such as you have here represented, and he calls them willow leaves, a term as little expressive as possible of any meaning, so that you may get nothing but the simple observation. You perceive from our drawing that a spot in the sun is not a mere uniformly black thing. It is very dark in the centre, but gets lighter as you approach the circumference, giving an idea of different coats of atmosphere till you come to the outer one, which is the most luminous. These are the appearances which present themselves under circumstances the most favourable for observations. It happens, however, that certain conditions of the atmosphere give rise to the appearance of what are called sun-boils. This is a most serious evil in regard to taking the sun photographically, the quivering of the atmosphere destroying the character of the rays, and thus interfering with accuracy of representation. It is, perhaps, not more than two or three times in the year that true observations can be taken. The spot represented in the drawing was observed and taken during seven or eight days in which time it had been going on revolving on its own axis, and not going with the sun itself. What a wonderful thing that a spot of that kind, many thousand miles in diameter, can be going on as a great continent! There are many other things about the sun equally wonderful, which men have learned to think of and imagine. Imagine! No, it is something better than imagination. The poet never could have conjured up in his mind what we now soberly speak of as making part of the sun's constitution and existence. It is a reason to give us thoughts of this kind.

But our time is gone. Before you leave I want to show you a photograph of the moon; for although I have been speaking of an eclipse of the sun you are still to understand that photography has advanced so far as to be able to give us representations of our own satellite. We cannot show you the whole of the moon at once; but we can show you a picture of the moon as taken by Mr. De la Rue, not by his hand, but by his mind, by means of photography; and if you apply the stereoscope you will there see that glorious body—for glorious she is, though by no means to be compared to the sun—as a perfect globe floating beautifully in space. You see here the most beautiful contrasts of light and shade, such as no ordinary picture could give and such as no imagination could supply. Here, I think, we must end our discourse. I hope you will accept what I have done to the best of my ability; and I am sure that we shall unanimously join in thanking Mr. De la Rue for all that he has accomplished.

SOCIETY OF ARTS.

Wednesday, May 1, 1861.

PETER GRAHAM, Esq., Member of Council, in the Chair.

Mr. JULIUS DAHLKE read a short, but on the whole, effective paper, at this Meeting of the Society, on "*Filtration and Filtering Media*," of which we propose to sketch the more important points.

As we all know, filters, in some form or other, have been employed from a very early period, but the historical part of Mr. Dahlke's paper is very imperfect, and does not present a good view of the progress of the art of filtration, as it should have done, to carry out its title properly. Thus, while a casual mention was made by the Lecturer of the porous stone and earthenware filters of the ancient Egyptians and Chinese, the early Roman arrangements for this purpose were not even named, nor were the more recent processes of Peacock, Paul, Rommerhausen, Thom, Leloge, Sterling, Beart, Murray, &c., referred to in any way. As regards the scientific aspects of filtration also, Mr. Dahlke is equally deficient, but as other parts of his paper are not without merit, we proceed to quote the same.

"During the past seventy years, gravel, sand, and charcoal, used as a mixture, have been the agents most in vogue amongst filter makers, and it is only lately that due attention has been paid to charcoal as the most efficient filtering medium. Its use is much more frequent now, because not only has it a powerful detergent effect, but it possesses also the peculiar advantage of not becoming foul, while it protects from decomposition other bodies in contact with it.

"It has been often asked why animal charcoal is so effective as a filtering medium? Some attribute this to the presence of so much carbon; but that this is an insufficient reason, is shown by the fact that, although coke contains more carbon than sand, yet it is not superior as a filtering agent.

"Animal charcoal filters about three and a-half times more rapidly than either coke or sand, while it is also greatly superior in this, that it removes many inorganic impurities held in solution, over which the former substances exert no power.

"It appears that the more porosity a filtering medium possesses in itself, the more rapidly does it filter, and the greater is the effect it produces on the water. The latter will be still more decided when, with a greater porosity, peculiar substances are combined.

"This leads me to believe that we may attribute the extraordinary filtering quality of animal charcoal to the fact that its principal component parts are lime and carbon, so combined as to secure a wonderfully fine porosity. Vegetable charcoal, although very porous, and containing far more carbon, has less effect on water.

"I have observed that another substance, of which I shall presently speak, and which (although of an entirely different origin) possesses great similarity in this respect, may in many cases be successfully substituted for animal charcoal. Indeed, there are doubtless numerous substances and compounds which may be used with as great effect. Do we not see that Nature supplies the most beautiful waters from limestone beds? It is hardly necessary to say, could we but imitate her action, that we should be able to do more in this as well as in other things, but we must content ourselves with as much success as our defective knowledge of her laws will permit us.

"Although we know of powerful agents for the removal of different impurities from water, circumstances may and do interpose which render it extremely difficult to obtain the medium in the requisite form for our purpose, and there is nothing yet discovered which will perfectly meet all the requirements of the case. Those who assert that it is possible to construct an apparatus to act as a universal filter for purifying any kind of water effectively whatever may be the impurities, remind me of the vendors of certain patent medicines, who vaunt their nostrums as capable of curing every disease. Their claims are about equally trustworthy.

"I should classify the art of filtration into three systems, viz.:—1st, where the action takes place simply on the surface of the filtering medium; and, where the whole bulk of the filtering medium is calculated to operate on the water, and the detergent effect in its most delicate form may be produced; and 3rd, where both of these systems are conjointly employed.

"The first system requires a filtering medium of such a fine porosity that its pores must be smaller than the minute particles composing the impurities suspended in the water. Such an agent of course must sooner become clogged, than a filtering medium of coarser porosity, and which is meant to act with its whole bulk on the water. But both systems employed together may prove to be useful in several instances, as in the case of domestic filters. The greatest failing of these is that they must become clogged, and the more they are liable to this, the more effectively they act. We often hear of self-cleansing domestic filters, but the fact is that no invention of the kind has been made yet, without involving complications too great for the purposes of ordinary domestic use.

"However, it is not difficult to make a filter for general domestic purposes—although the effective self-cleansing of such an apparatus is still a problem to be solved.

"If the filtering medium employed in this case be solid, and of a fine porosity in its upper part, the clogging impurities will not only be retained on the surface, but may be easily removed by scraping; and then, if the lower part of the filtering medium be prepared of a material capable of producing a detergent effect, it will act the more readily through not being interfered with by the rougher and clogging impurities.

"It should be remembered, too, that in most cases we have here only to deal with some rougher impurities which have found their way into the water on its passage from water works, or other source, to the tap of the consumer.

"Being deeply interested in the subject of filtration, I have never omitted an opportunity of carefully inspecting those house-cisterns which came under my observation; I have, however, seen but few to which the attention necessary to secure the due cleansing had been paid. Most of them were loaded with mud, and in some of them I actually noticed the growth of vegetation (fungi). I conclude, from my observations, that hardly one-fourth of the house-cisterns in London are in such a condition as to afford the consumer a supply of wholesome water like that which flows from the main.

"The difficulty, or I may say the impossibility, of keep-

ing water which is stored in cisterns entirely free from accidental contamination, should lead us to provide a domestic filter capable of removing chemical impurities, as, for example, any lead which may be held in solution; in fact, the practice of filtering water preserved in cisterns and intended for domestic use cannot be too warmly recommended.

"To remove lead from water, Professor Faraday recommends the practice of stirring up animal charcoal with the water so contaminated, the same being then allowed to settle. I have found, however, that, by using this material in a manner to be described hereafter, I never failed in producing the same effect by means of filtration.

"It is easy enough to purify small quantities of water, but the greater the quantity the greater are the difficulties of purification, especially when a certain chemical effect has to be produced.

"It will not be necessary for me to dwell upon the filtering processes required for large waterworks, as the supply is generally taken from such sources that the common sand filter-bed answers the purpose; and where the water is too hard for domestic uses, the beautiful process of Dr. Clark will meet and remedy the evil.

"Experience shows that it is not prudent to adopt the same means of purification for every kind of water, and I should make a difference in the treatment of the water used for domestic and that employed for manufacturing purposes. In the latter it will be often of the greatest importance to have the water as pure as possible, whereas certain so-called impurities in water may not be at all injurious to health. When we consider that no one would call human blood impure which contained 420 grains of saline matter per gallon, I do not know that we are justified (of course, speaking in relation to health) in calling water impure which contains small quantities of certain saline matters, particularly when we have no medical evidence that the small portions of them drunk in such water ever did any harm. Besides which, it should be remarked that the quantity of lime and magnesian salts drunk in water must be greatly exceeded in amount by that which enters the system in the food."

Mr. Dahlke had better have omitted this last paragraph, his knowledge of our language not being sufficient to show him the true signification of the words "pure" and "impure." There are a good many substances essential to the legitimate composition of our bodies that cannot be considered other than "impurities," if present in the water we drink; there is, moreover, abundance of medical and social evidence that large quantities of lime and saline matters in drinking water are productive of decidedly injurious effects, especially upon the skin, kidneys, and digestive organs.

Mr. Dahlke next said that "too pure water is distasteful, and unfit for drinking purposes," citing an illustrative case of some flat-tasting, remarkably pure water, which he had rendered more palatable by adding to it "some finely-dissolved organic impurities," and then filtering through animal charcoal!

Our author prefers animal charcoal to all other filtering media, and regrets that no practical method is yet known of moulding it into blocks without diminishing its powers. Charcoal, he said, as regards its filtering qualities, stands to coke as 15 to 4, and all attempts at solidifying it by calcination with pitch, tar, &c., have failed in practice, owing to the glazing effects of the bitumen, which greatly impairs its action.

Mr. Dahlke's filter we shall shortly describe, as it appears to possess certain advantages over others of the same class that render it well worthy of notice; after various trials he found that the residue, after distillation, of the well-known Torbane-hill mineral, with a small addition of fine clay, will, if saturated with fatty or oily

matter,² and calcined, furnish a very powerful filtering medium, capable of reducing the hardness of water, and removing its colour and odour. He also adds bone-dust both to improve the quality of the "filter-blocks," and in order to regulate their degree of porosity with greater precision. We must now, however, permit Mr. Dahlke to describe his own filter more particularly:—

"Supposing 5000 gallons of water are daily required to be purified, that the water supplied contains nine grains of organic matter per gallon, has a bad smell, and is of seventeen degrees of hardness, I should employ an apparatus of which a woodcut is here given.

"The upper part is a tank made from slate, completely closed, and is divided into two compartments by means of a solid filter block with one inlet, and one outlet for each of them. The supply-pipe is provided with a three-way cock, *x*, which allows the necessary arrangement to be made for admitting the water to one compartment of the tank, and for causing it to pass into the other through the filter-block. If, for instance, it enters at *A*, it has to pass through *x* into *B*, flow off by *DD'*, and through *K* and *H* into the second apparatus.

"This tank, being only intended to free the water from the rougher and clogging impurities, its action is to be reversed as often as may appear necessary in order to remove the collected sediment. This is easily done by shutting off the supply-pipe for *A*, and opening that for *B*; but before the water is allowed to enter the connecting pipe of the second apparatus, the accumulated impurities must be removed through the opening of the corresponding plug *G*, and, that it may flow off easily, the bottoms of the two compartments are inclined towards the plugs.

"The two walls of the tank which face the filtering medium, are so fixed, that they can be opened from time to time, in order that the surface of the filter may be scoured, it being of such a consistency that its surface can be easily abraded by rubbing with hard stone.

² We would suggest blood, or milk, as more likely to answer the purpose.—Ed.

"The water is thus freed from its coarser organic impurities, so far that they cannot possibly clog the second apparatus, which is thus retained almost entirely for chemical action on the water. It consists of a vessel which is also completely closed, with one inlet (*w*), and one outlet (*e*), divided from *m* to *r*, and fitted in the following manner:—*r* is a solid filter-block, cemented into the apparatus and covering the whole surface of the body *a*, thus forming the top part of this filter; it is of much finer porosity than the filtering-block in the tank, in order to separate the finer particles of organic matter from the water. The space *a* is filled up with coarse granular charcoal and a preparation of the Torbane-hill mineral spoken of, intended to operate upon the water so as to remove those matters held in solution, which impart colour, smell, and hardness. *z* is a solid filter-plate, of a more neutral character, also cemented into the vessel to hold together with *r*, the packing of the apparatus.

"The reason why the two materials which fill *a* are employed in a rather coarse grain, is, because the oxidation of several of the impurities taking place during the filtering process, will produce considerable quantities of gases which would soon accumulate in a finer medium and interfere with the rate of filtration, wherefore I rather prefer employing the mixture in a thicker layer.

"The dimensions of the apparatus, and the different filtering media employed in this case, will be 3 feet square by 4 inches in thickness for the filter-block in the tank; each compartment of Apparatus No. II. to be 18 inches high by 2 feet square (internal measure); its fittings are: the plate *r*, 3 inches thick, *a*, 2 feet, and *z*, 3 inches.

"The first clogging in Apparatus No. II. will take place on the surface of *r*, which can be easily avoided by removing the corresponding cover of the vessel, and rubbing the surface of *r* with a piece of hard stone, to which it will slowly yield, and thus be easily freed from its clogging matters, which cannot penetrate into it, the porosity of the filter-cake being too fine.

"The filter-block in the tank is so fixed that it can be taken out and replaced without much inconvenience, should it become worn out.

"The apparatus thus arranged is calculated for not less than 12 feet pressure, and its effect on such water as we supposed to have for illustration will be as follows:—Organic impurities reduced to about half-a-grain per gallon, no trace of smell or colour remains, and its hardness is reduced to about 7 or 8 degrees.

"With regard to the continuance of the chemical effect, I admit that this must have its limits; however, from the fact that the rougher clogging impurities are so easily removed from the apparatus, and that the quantity of the inorganic impurities which will be absorbed must necessarily be comparatively small, a good portion of them escaping in the form of gas, I do not hesitate to assert that it can be successfully employed, for a considerable time, before the filtering agents get exhausted, and repacking is required.

"I do not believe it would be possible to work such a quantity of water so effectively and lastingly in such a small apparatus, if the whole of the filtering medium were to be used in a loose state, as its porosity in the latter case could not be condensed to the state of fineness required.

"This apparatus being only meant to serve for the special purpose I spoke of, it is obvious that it will have to be altered according to circumstances, both as regards the filtering agents to be employed, and its mechanical arrangements.

"If the quantity of water to be filtered be so great that a very large filter-bed is required, I prefer employing the preparation of the Torbane-hill mineral, as described, in a granular state, rather than sand; for this reason, that it filters more than three times as quick, and is five times as light as the latter; consequently a ton of it will, by a layer of equal thickness, filter about sixteen times the

quantity of water that a ton of sand would filter, with the advantage that the filtering would produce at the same time a greater decolorising effect and a considerable softening of the water. A clogging from the precipitation of chalk is not likely to take place, as this substance is separated in a crystalline and granular state. Moreover, those particles of the material which become saturated with organic impurities may, through calcination, regain the greater part of their former efficiency."

Omitting the concluding paragraph of the Paper, which is unimportant, we have now to present to our readers the "cream" of the discussion which followed.

Mr. SPENCER rose first, to deliver a speech, of which the chief object seemed to be, to lay claim to Mr. Dahlke's invention or application entirely. He had broken open one of the filters in question, and found the filtering medium contained about ten per cent. of the magnetic oxide of iron, to which, he said, all its virtues were due. He had determined (quantitatively?) the presence of this substance by means of the magnet, and accused the Author of the paper of infringing his (Mr. Spencer's) patent.

Mr. ATKINS set forth the merits of "carbon" *per se*, as a filtering agent, of which he had manufactured some 40,000 or 50,000 blocks, and proceeded to praise the Moulded Carbon Company and their manufactures in high terms.

Dr. WALLER LEWIS bore testimony to the efficacy of the filter supplied by Mr. Dahlke to a very large public department, as to its powers of deodorising and decolorising water. It was new to him to hear that too pure water was distasteful; and he was afraid Mr. Dahlke was assuming an untenable position. He thought inhabitants of towns were no judges of water, as their palates were disorganised by the impure water supplied to them. He had tasted the water of Lake Bala in North Wales, containing only $\frac{1}{4}$ grains of mineral matter per gallon. Many persons did not like it at first, if they had been accustomed to London water.

Mr. PAINTER dwelt upon the good qualities of a mixture of silica and carbon, and of the balls of the Moulded Carbon Company. These balls were cleaned by blowing air through them—a superior plan to that of Mr. Dahlke, he thought.

Mr. DANCHELL preferred animal charcoal to anything else, and had abandoned all other filtering media.

Mr. WENTWORTH SCOTT said he had been called upon to make various experiments upon the relative merits of animal charcoal and prepared carbons of several kinds, as regards their power of absorbing organic matter, which resulted in favour of the first-named substance. The Moulded Carbon Company's balls were subject to the defect of having in many cases their central cavity greatly on one side, thereby modifying their action injuriously. He recommended the *platinising* of the balls—a simple process—for waters containing much organic matter.

Mr. MOROAN remarked that the public were the best judges of filters in the end. He regretted that scientific discussions were so frequently sullied by personalities, and commented severely, but justly, upon Mr. Spencer's speech.

After a brief reply from Mr. DAHLKE, a vote of thanks was passed to him, on the motion of the Chairman, for his Paper, and the meeting then adjourned.

NOTICES OF BOOKS.

Elements of Agricultural Chemistry. By THOMAS ANDERSON, M.D., F.R.S.E., F.C.S., Professor of Chemistry in the University of Glasgow. Edinburgh: A. and C. Black. 1861.

In many respects this is an admirable manual for the attentive study of the farmer. It contains a full and fair

account of the relation of chemistry to agriculture, telling us what advantages the latter may reasonably expect from the former, and what it may not. The reader is gradually introduced, by easy stages, to such technicalities as are necessarily involved in the subject,—for the Author writes for those who are unacquainted even with the elementary facts of chemical science.

The book opens with an account of the constituents, organic and inorganic, of plants. The proximate vegetable and animal constituents, and the processes whereby these are originated by organic action on the soil and air, are described. The chapter on the General Principles of Manuring is crowded with facts, accurately but cautiously given. The distinctions made between *special* and *general* manures are remarkably sound. The following are the titles of the remaining chapters of the volume:—The Composition and Properties of Farm-yard and Liquid Manures—of Vegetable Manures—of Animal Manures—and of Mineral Manures—The Valuation of Manures—The Rotation of Crops—and the Feeding of Farm-Stock. Almost every page gives evidence of Dr. Anderson's large experience as a practical agricultural chemist. His views on the various controversies connected with this important branch of practical science are temperately expressed, and supported by a large number of well-contrived experiments.

The book, for the most part, is clearly written. Occasionally, however, we meet with ungrammatical or awkward constructions in it, which detract from its general literary excellence.

CORRESPONDENCE.

Dead Black for Metal Work.

To the Editor of the CHEMICAL NEWS.

SIR,—You would be doing a good many Riflemen a service if you would inform us of the best method of staining the sights of our rifles black. These sights are black when new, but after a little wear become bright and it is then difficult when the sun shines upon them to take so correct an aim. Some persons rub a little Prussian blue on them, but this is a dirty plan, and rubs off on our hands and clothes. Some method of giving them a permanent dead black stain would be the thing.

I am, &c.

A RIFLEMAN.

Chemical Notices from Foreign Sources.

1. MINERAL CHEMISTRY.

Transformation of Nitrates into Ulmates.—

M. Paul Thénard put some solution of glucose and some nitrate of baryta into a tube and heated them to 200°. He obtained thereby a colourless liquid and a white powder, which, when exposed to the air, browned and blackened or took the colour of the ulmic compounds. This seemed in contradiction to the already known fact that in the soil ulmates are converted into nitrates. But a further investigation has convinced M. Thénard that both processes go on simultaneously in the earth. That on the surface of the ground ulmates are converted into nitrates, and in the subsoil nitrates are changed into ulmates. Iron, according to the author, appears to be the carrier of the oxygen, which effects the transformation.

Comparative Action of Nitrates and Ammonia on Vegetation.—

We may here quote the results of some experiments by Ville (*Comptes-Rendus*, t. li. p. 874), which go to prove that nitrate of potash has a much greater influence on the growth of plants than ammonia—that in fact the nitrogen of nitrates is much more assimilable than the nitrogen of ammonia.

Solubility of Different Forms of Silica in Potash.

—Rammelsberg made a series of experiments (*Bericht der Akad. d. Wissenschaft zu Berlin*, 1860, s. 758) to ascertain whether a strong potash ley afforded a means of distinguishing between quartz and opal. Fuchs had already made known the fact that while quartz is attacked with difficulty by a potash solution, some opals are easily dissolved by it. Rammelsberg's object was to see whether the amount of each could be estimated by the same means. In this respect the experiments do not seem to be conclusive. Some opals dissolve very slowly; and the rate at which the different forms of silica are dissolved is not so constant as to allow us to separate in this way one form from another.

Phosphate of Cobalt and Zinc.—Gentele has analysed (*Journ. für prakt. Chem.*, Bo. lxxxii., s. 58) some pigments used for colouring porcelain. One was a very pure dark blue, of extraordinary beauty, in which the author found CoO 15.09, ZnO 18.24. The flux contained PbO 26.85, SiO_2 24.46, Al_2O_3 1.24. The blue was perfectly dissolved from the flux by acetic acid, and this fact led the author to the discovery that the cobalt and zinc oxides were in combination with phosphoric acid. The colour may be made in the following way: to a solution of ordinary phosphate of soda is added first a solution of sulphate of zinc, and then of sulphate of cobalt. A green precipitate falls which turns blue on the addition of more sulphate of cobalt. A certain amount of phosphate of soda must, however, remain in excess. The blue precipitate becomes green again if more sulphate of zinc is added, and again blue on the addition of the cobalt solution. The supernatant liquid remains red. The washed precipitate is a dark blue with just a suspicion of red, but after ignition it is a pure blue. An analysis of the precipitate dried at 30° gave:—

Zinc oxide	41.95
Cobaltous oxide	12.97
Phosphoric acid	33.25
Water	12.06

which gives the compound $3(3\text{ZnO} \cdot \text{PO}_5 + 3\text{HO}) + 3\text{CoO} \cdot \text{PO}_5 + 3\text{HO}$.

II. ORGANIC CHEMISTRY.

Peculiar Product from some Coal Oils.

MM. Riche and Baidy have examined with some minuteness (*Bulletin de la Société Chimique de Paris*, No. I. p. 14) a yellow body obtained when certain coal oils are treated with nitric acid. As first obtained, it is a solid black mass smelling strongly of nitrobenzine, and staining the skin yellow like picric acid. Purified by repeated filtration through moistened bibulous paper, to remove the black viscid oil, crystals of a deep yellow colour are procured which no longer smell of nitrobenzine. Their analysis gave results which led to the formula $\text{C}_{12}\text{H}_9\text{N}_3\text{O}_{12}$. On drying the crystals in a vacuum for four days, they broke up and became reddish. The analysis of them in this condition gave the composition $\text{C}_{12}\text{H}_9\text{N}_3\text{O}_{10}$, showing that the crystals had lost two atoms HO . The exact nature of this body the authors have not been able to determine. It gives precipitates with salts of most of the metals, and the compounds formed with lead and silver easily crystallize. The silver compound blackens in the light, and explodes with violence at a very slight elevation of temperature.

Reactions of Cinchonine.—A small quantity of a solution of yellow prussiate of potash added to a solution of a salt of cinchonine gives a precipitate. If the mixture be carefully heated for some time the precipitate redissolves, and when the solution cools, numerous gold-yellow crystals deposit. These crystals Dr. Seligsohn found (*Medicin Centralzeit.*, 1861. Stück 17, s. 129) to be composed of one atom cinchonine and one atom ferrocyanogen. The solution of the cinchonine salt

must not be acid, nor must it be warm when the prussiate is added. Cinchonine may be detected in the urine by this test. The urine must be evaporated to dryness on a water bath, the residue treated with alcohol, the alcoholic filtrate evaporated to dryness, and the residue from it dissolved in water. The solution of prussiate of potash is then cautiously added: the solution remains clear at first, but after a time the golden-yellow crystals appear on the sides of the test glass.

Green Dye from the Rhamnus Catharticus.

M. Charvin has discovered in the *Rhamnus Catharticus* a green dye which seems to bear a great resemblance to the Chinese green *Lo-kao*. It is prepared in following way:—The bark of the buckthorn is put into boiling water and after boiling some minutes the contents of the vessel, bark and water together, are turned into an earthen pan, and covered up that they may cool slowly. After some days the liquid, which is of a brownish yellow colour, is poured off, and clearlime water is added to it. It is then exposed in shallow dishes to air and light under the influence of which the colour soon changes to green, and a deposit of the same tint settles in the dishes. Carbonate of potash is afterwards added, which produces a green precipitate, the fluid taking a dark brown colour. When the precipitate has deposited, the fluid is poured off, and the precipitate collected on a filter and dried. Glénard in a report addressed to the Lyons Chamber of Commerce (*Bulletin de la Société d'Encourage.* November, 1860) has recommended the discoverer of this dye for the prize of 6000 francs offered by the Chamber in 1857, for a colour like the Chinese green extracted from a home plant.

ANSWERS TO CORRESPONDENTS.

*. In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

*. All Editorial Communications are to be addressed to Mr. CROOKES, and Advertisements and Business Communications to the PUBLISHERS, GRIFFIN, BORN & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

Vol. II. of the *CHEMICAL NEWS*, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1861, and will be complete in 26 numbers.

J. C.—The distillate contains a good quantity of benzol. The method we gave was not intended to separate all, or even the greater part, of the benzol from the liquid, but merely to enable the relative values of different samples to be ascertained. That which yielded the most distillate below 212° being the best. You will find no work so good as the published volumes of the *CHEMICAL NEWS*.

G. F. A.—We are glad to hear from an old friend. Perhaps our opinions coincide with his, but we must not exercise authority too harshly.

Phœnix.—Wood may be stained to imitate rosewood by boiling 8 oz. of logwood in 3 pints of water until reduced to half. Apply it boiling hot three times, letting it dry between each. Afterwards put in the strokes with a camel hair pencil dipped in a solution of copperas and verdigris in decoction of logwood.

A Constant Reader.—Boil 1 oz. of logwood, $\frac{1}{2}$ oz. sumach, and 1 drm. of copperas in 4 pints of water.

Tasmanian Wheat.—The letter of our correspondent, "F.C.S." (in our last Number) was founded upon a misconception, resulting from a typographical error in Mr. W. Scott's Analysis of Tasmanian Wheat, published in No. 76. The figures showing the per-centages of Water, Ash, Nitrogenous Matter, and Carbonous Matter should have been printed in larger type than the rest, as should also the total "100.000" which is derived from these four parts alone.

R. J. Rutter.—Apply to the Secretary, at Burlington-house, Piccadilly.

Erratum.—P. 327, Article "Coloured Derivatives of Naphthalene," sixth and eleventh lines from bottom, for *nitrate* read *nitrite*.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Amounts of Lead contained in some Silver Coins, by Messrs. CHARLES W. ELIOT and FRANK H. STOREY.

(Continued from page 320.)

THE residue of gold and filter paper left after dissolving the carbonate of lead in nitric acid for the final lead determination, was in each case incinerated, and then fused with carbonate of soda before the blowpipe. A distinct button of metallic gold was obtained in every instance. The amount of gold obtained varied, however, to a very considerable extent: it was abundant in the American and Spanish coin, less was observed in the English and Mexican, and but little in the French coin or the American fine silver.¹

The silver of the French coin was undoubtedly prepared by the sulphuric-acid process,² in which the granulated alloy of silver, gold, copper, &c., is dissolved in hot concentrated sulphuric acid, and the silver subsequently precipitated, by means of metallic copper, from a somewhat diluted hot solution of the sulphate of silver thus obtained. Since ordinary commercial sulphuric acid³ is used in this operation, it is not strange that a portion of the lead with which it is contaminated should

be transferred to the silver. The lead salt is, perhaps, reduced by the metallic copper, in the manner so well described by Odling, in his Memoir "On the Reciprocal Precipitations of the Metals."⁴ It is, moreover, not impossible that some sulphate of lead may fall when the acid liquor is diluted, and become mixed with the precipitated silver. It is not credible, however, that the lead in the coin can have been derived from the copper used to form the standard alloy; for this supposition would imply that copper of very inferior quality had been employed. According to Karsten,⁵ copper which contains but one per cent. of lead is utterly unfit for manufacturing purposes, since it cannot be worked at any temperature. Now, the least amount of lead which we found in fifty cents' worth of American silver is 0.0253 gram. in 10 half-dimes of 1853. These 10 half-dimes contain 1.243 gram. of copper, and if this metal had been the source of the lead, it must have contained more than two per cent. of that impurity.

We are ignorant of the process of preparing silver which was in use at the British Mint in 1816. Perhaps the silver in the coin of that date was obtained by cupellation, and it is well known that silver so obtained almost always contains lead.⁶

The silver of the Spanish and Mexican coins was, doubtless, prepared by the American system of amalgamation.⁷ In this process, speaking in general terms, it would appear that silver is reduced by means of metallic mercury from a solution of chloride of silver in chloride of sodium, the amalgam which is formed being exposed meanwhile to the action of chloride of copper and perchloride of iron.

It is to be inferred from the investigations which we have cited, that, under these circumstances, the amalgam should be almost entirely free from any contamination with the more strongly electro-positive metals.⁸ It

¹ Besides the quantitative analyses recorded above, which have been made by this method, it should be mentioned, that in several qualitative experiments upon American coins, by the method as described or slightly modified, indications of lead were obtained in every instance. The same remark is true of two qualitative analyses,—one of a dime and another of a quarter-dollar,—made as follows:—the coin having been dissolved in nitric acid, and the insoluble black residue of sulphide of silver and a little gold separated by filtering, the solution was mixed with pure acetate of soda (see Fresenius, *op. cit.*, p. 428, § 163, i. 7) to prevent precipitation of chloride of lead in subsequent operations, and the whole heated over the water-bath; the silver was then precipitated with dilute chlorhydric acid, and the chloride of silver collected upon a filter and washed. Through the filtrate sulphuretted hydrogen was passed, the mixed sulphide of copper, lead, and gold collected upon a filter, treated with nitric acid, the acid solution, evaporated to dryness, the residue taken up with water, and the solution filtered; in the filtrate lead was detected, while the residue contained gold. With regard to this residue of gold, which has also been alluded to in the text, it should be remarked that it has been entirely neglected by many analysts who have published determinations of the amounts of gold in various silver coins. Indeed, it would appear as if the fact were not generally known to chemists, that nitric acid can dissolve a little gold (as it can platinum), when an alloy containing a small quantity of gold is treated with this acid (compare Mulder, *op. cit.*, p. 159). Another common error of analysts has been, to class as "gold" the dark-coloured residue which is usually left when silver coin is dissolved in dilute nitric acid. This precipitate does, in fact, generally contain a little gold, though in our own experiments by far the larger portion of this metal passed into solution in the nitric acid, and was separated at a subsequent stage of the analysis, as has been described; Gay Lussac (*Ann. Ch. et Phys.*, 1836, [2.] liii. 334) long ago showed that it is principally composed of sulphide of silver; to which fact attention has also been called by Mulder, in his excellent little treatise, just cited, p. 178.

⁶ Authorities differ as to the amount of lead contained in crude cupelled silver ("lightened silver," *argent éclairci*, *Blacksilver*). According to Berthier ("Essais par la Voie Seche," Paris, 1848,) li. 724, it contains, on an average, only 1 per cent. of lead. Kerl ("Handbuch der metallurgischen Hüttenkunde," (Freiburg, 1855,) iii. 152), on the other hand, says that it contains from 5 to 10 per cent. of impurity; and according to Karsten ("System der Metallurgie," v. pp. 200, 201) Blacksilver contains, at least, 12 per cent. of lead, and often more, the proportion of lead to silver being entirely dependent upon the temperature of the cupelling furnace. Since such silver is unfit for use, it is refined by small portions, either by a second cupellation at a high heat, or by melting it in crucibles with saltpetre and borax, or some other flux (Kerl, *op. cit.*, iii. pp. 181 to 198); but it appears to be impracticable, or at least not advantageous in practice to remove the last traces of lead from the silver by either of these processes. (See Kerl, *op. cit.*, i. 224; or Plattner, "Probirkunst mit dem Löthrohre," (Leipzig, 1853,) p. 403).

⁷ Described by Humboldt in his "Essai Politique sur le Royaume de la Nouvelle Espagne," (Paris, 1811,) li. 558. See also Karsten, "Abhandlungen der phys. Klasse der Akad. der Wissenschaften zu Berlin," 1828, p. 1; and "Karsten u. Dechen's Archiv für Mineralogie," etc., 1829, i. 161; and again, *ibid.* xxv. 178, and in *Dingler's Polyt. Journ.*, 1852, cxxvi. 357. Compare the subsequent statements of Boussingault, *Ann. Ch. et Phys.*, 1832, [2.] li. 350.

⁸ In the European system of amalgamation, as practised at Freiberg, in Saxony, where the silver is reduced from its chloride by metallic

would seem, indeed, that the American system of amalgamation furnishes purer silver than is obtained by any of the other processes which are employed upon the large scale.

So far as concerns the occurrence of lead in the silver coin of our own country, it could probably be mainly, if not altogether, avoided, by employing zinc free from lead, such as is manufactured in Pennsylvania, as we have already described in our Memoir.

It is interesting to observe that the occurrence of lead in some of the silver coins of the ancients⁹ has been thought to indicate "that the process of separating lead and silver was less perfectly executed in the ages of antiquity than is at present the case."¹⁰ Yet, in none of the recorded analyses of ancient silver coins to which we have had access have we been able to find that any one has detected so large an amount of lead in these coins, as we have shown to occur in American fine silver of the year 1860, if we except a single analysis by Professor Draper, who found nearly 3 per cent. of lead in a silver coin of Hadrian. The greatest per-centage of lead observed by Brüel (the author of the remark just quoted) was only 0.12. It is probable, however, that the methods of analysis—none of which are recorded—employed for separating lead from silver by the chemists to whose labours we have referred, were less delicate than the process which we have ourselves made use of.

It is interesting also in this connection to observe, that the American system of amalgamation, which at one time—before its peculiar fitness for the circumstances of the case in which it is employed had been recognised—was so frequently criticised by European metallurgists, affords silver which is less strongly contaminated with lead, and is probably purer in other respects than is produced by any other process of manufacture.—*Proceedings of the American Academy of Arts and Sciences.*

On the Preparation of Hydriodic and Hydrobromic Ethers by the Substitution of Amorphous for Normal Phosphorus, by M. J. PERSONNE.

In a paper published in 1857,¹¹ I showed that red, or amorphous phosphorus, behaved with various chemical agents in the same manner as normal phosphorus, but that its reactions were less intense. These facts have led me to substitute amorphous for normal phosphorus in the preparation of various chemical compounds, the production of which has hitherto been attended with some difficulty, on account of the energy of the reaction between the normal phosphorus and the bodies acting upon it. I intend treating of hydriodic and hydrobromic ethers, and also hydriodic acid. The results obtained are so clear and so easily practised, that by publishing

iron instead of quicksilver, a similar degree of purity in the silver is not to be expected. (For analyses of such silver, "Tellerhäuser," see Karl, *op. cit.*, i. 234.)

⁹ Walchner, Schwigger's *Journal für Ch. u. Phys.*, 1827, ii. pp. 204, 205. J. W. Draper, *Silliman's American Journal of Science*, 1856, [1.] xxix. 160. *Berzou's Journal de Pharmacie*, 1859, xxv. 503. Brüel and Hausmann, "Karsten u. Dechen's Archiv für Mineralogie," &c., 1844, xviii. 505; also in *J. pr. Chem.*, xxx. 334. J. W. Mallot, *Transactions of the Royal Irish Academy*, 1853, xxii. 319. Brüel and Hausmann refer also to earlier determinations of lead in antique coins by Klapproth (probably in his "Beiträge zur chemischen Kenntniss der Mineral-Körper," 1795-1798, B. vi.), and by Goebel (doubtless in his brochure, "Ueber den Einfluss der Chemie auf die Ermittlung der Völker der Vorzeit," &c., Erlangen, 1842); but they do not indicate precisely where these analyses are to be found, nor have we any means of ascertaining this point.

them I hope to render a real service to chemists, who so frequently have occasion to employ these compounds, especially in the preparation of compound ammonias and organo-metallic radicals.

Hydriodic Ether.—If the preparation of hydriodic ether has been facilitated by the improvements recently introduced by MM. E. Kopp, F. Marchand, Soubeiran, and lastly by M. Hofmann, the process is, notwithstanding, just as tedious, since it is always necessary to add the phosphorus very gradually to the alcoholic solution of iodine. Thus, according to M. Marchand, it requires three days to prepare the quantity of hydriodic ether furnished by 680 grammes of iodine and 200 grammes of phosphorus, that is to say, about 800 grammes. If, on the contrary, amorphous phosphorus is employed, the operation becomes exceedingly easy and surprisingly rapid. The following is the mode of operating:—

In a tubulated retort, fitted with a receiver, place 30 grammes of powdered amorphous phosphorus, and 120 grammes of absolute alcohol; then add, at two separate times, and with an interval of a few minutes, 100 grammes of iodine. Place the retort on a sand-bath, and proceed with the distillation until the distilled liquor ceases to be precipitated by water. The distilled product is scarcely coloured by the iodine, and if washed with water containing some drops of solution of potash it becomes perfectly colourless. The weight of the obtained product, when washed to expel the alcohol, corresponds exactly to the theoretical quantity. Thus, from 100 grammes of iodine I have obtained at one operation 125 grammes; at another 120 grammes; and at a third, 118 grammes—the theoretical quantity being 123 grammes.

In operating thus it requires less than a quarter-of-an-hour to prepare more than 150 grammes of hydriodic ether, and I feel assured that 1 kilogramme could be prepared in an hour. The quantity of amorphous phosphorus employed is larger than is really necessary, but no inconvenience results from this, because it remains in the retort, soiled, it is true, by the phosphoric and phosphorous acids, but requiring only washing in hot water to render it perfectly fit for another operation.

Hydrobromic Ether.—The preparation of hydrobromic ether with normal phosphorus and bromine is attended with even more danger than that of hydriodic acid,—so much so, indeed, that this method of preparing it has been almost discarded, and it has been principally obtained by treating alcohol by excess of bromine, and afterwards separating the hydrobromic ether by distillation from the bromal and ethylene and perbromated products. If, by this method, there is no danger, there is at least the inconvenience of losing a great quantity of bromine. The following is the method of operating with amorphous phosphorus:—

To 40 grammes of amorphous phosphorus, and from 150 to 160 grammes of absolute alcohol placed in a tubulated retort fitted with a receiver, add by degrees 100 grammes of bromine by means of a funnel tube, with a tapering and slightly recurved extremity immersed in the alcohol; the bromine must only be added by degrees, because of the energy of the reaction, which would cause a great part of the product to distil before the whole of the bromine had been added. It is advisable to place the retort in a cold water-bath, and to cool the receiver by a current of water. When all the bromine has been added to the liquid, remove the funnel, pour into the retort the small quantity of liquid which the temperature of the reaction has caused to pass into

the receiver, then proceed at once with the distillation, operating in the same manner as with hydriodic ether.

This operation is as easy and as little dangerous as the former, but it requires double the time. The theoretical quantity is obtained as nearly as possible; thus with 100 grammes of bromine I have obtained, at one operation, 122 grammes; at another, 115 grammes; and at a third, 120 grammes of product—the theoretical quantity being 136 grammes. This slight difference is occasioned by the unavoidable loss of bromine while adding it by degrees to the alcoholic liquid.

Hydriodic Acid.—Notwithstanding M. Deville's improvements in the preparation of gaseous hydriodic acid, my opinion is that it will be found to be more convenient and expeditious to prepare it with amorphous phosphorus. In fact, it is enough to place a sufficiently large quantity of amorphous phosphorus in a tubulated retort with a glass stopper, to cover it with a layer of water, and to add the iodine in adequate quantity, to obtain by the aid of a slight degree of heat a regular current of gas, perfectly free from iodine vapour.

Now that amorphous phosphorus is used for industrial purposes, and is easily procurable, I am persuaded that valuable results may be obtained by substituting it for normal phosphorus, in most of the reactions in which this body takes a part.—*Comptes-Rendus*.

TECHNICAL CHEMISTRY.

On the Chemical Composition of Cast Iron and Steel,
by M. FREMY.

(Continued from page 332.)

THE object of my previous publications on steel was to prove that the part played by nitrogen in acieration has been hitherto misunderstood, and that nitrogen is not only a very active cementation agent, but that it remains in the metallic compound. Hitherto, my papers have been almost exclusively dedicated to synthetical operations, and to experiments in the laboratory. In this communication it is my intention to prove by means of chemical analysis that steel ceases to exist when its nitrogen is expelled, and that all practical operations tend to confirm my previously published opinions touching the constitution of steel. I will first describe an analytical experiment which I think will satisfy the most exacting critics.

My former studies on nitrides have convinced me that hydrogen can carry off in the state of ammonia the nitrogen contained in nitride of iron; after establishing the fact that steels are nitrogenised, I concluded that hydrogen also could decompose steel, and re-convert it to the state of iron. Experience has confirmed this surmise. I present to the Academy a plate of cast steel of the finest quality, a part of which only has been submitted at red heat to the action of hydrogen. The operation occupied three hours, and during the whole of this time the steel constantly disengaged ammoniacal vapours, and probably other nitrogenised alkalies, the vapour of which smells like burnt horn. The portion of the specimen submitted to the action of hydrogen, and which has parted with its nitrogen, lost entirely the properties of steel, being transformed into soft and wonderfully malleable iron, which tempering had no power to modify; while the other portion of the plate which had not been de-nitrogenised preserved all the characteristics of steel.

In this transformation steel loses about 1 per cent. of

its weight. This diminution in weight probably represents all the substances existing in steel besides those found in iron, for ammonia induces the conversion of the carburetted compounds into cyanide of ammonium. The constitution of steel may be considered, then, as established both by synthesis and analysis. Iron is converted into steel by nitrogenising it in presence of carbon; and steel is re-converted to iron by withdrawing the nitrogen by hydrogen. The results from the experiment here described may be easily foreseen. To preserve the valuable properties of steel it should be kept from contact with any substance capable of depriving it of nitrogen.

In manufacturing fire-arms from cast-steel, the action which the gases proceeding from the detonation of the powder may exert upon steel should be taken into account. It is probable that nitrogen inheres with greater tenacity in some kinds of steel than in others; for example, it is not so difficult to expel it from puddled as blistered steel. By the action of hydrogen on steel we get a soft iron which may perhaps be usefully applied to the construction of certain magnetic apparatus.

Several members of the Academy have asked me to examine a very malleable iron obtained from a modification of steel; probably this metal is identical with that produced by expelling the nitrogen from steel, as in the preceding experiment.

After decomposing steel by depriving it of nitrogen by means of hydrogen, it seems interesting to inquire to what extent the metal is susceptible of modification by the action of combustion gases. The influence of carbonic acid ought to be carefully studied in this respect. I find that steel quickly loses its carbon by the action of carbonic acid, which reduces it to the state of nitrogenised iron; an excess of carbonic acid burns the metal completely. All steel-workers know that this body is liable to destruction; as they express it, "it burns itself" when too long exposed to the action of the gaseous products of combustion. This modification is evidently due to the oxidising compounds carrying off the carbon. All the methods employed in manufactories to recover burnt steel have probably for their object to restore the carbon taken from it by the gases. I believe, however, that this restitution is always incomplete, and that a steel thoroughly burnt can never be restored; I even think that, under certain conditions, heat alone suffices to make a physical modification in steel, which tempering in a fatty body would to some extent destroy. The alterations which steel undergoes when "burnt,"—that is to say when carelessly heated,—may be due either to chemical decomposition or simple physical modification.

I turn now to the examination of some practical, established facts, tending to confirm my opinion in reference to the constitution of steel. The supporters of the old theory of acieration, who still consider steel as a carburet of iron, will deny the possibility of producing a nitride in a medium containing nothing but iron and carbon. I am about to show that in cementation cases, far from being submitted to carburising influences exclusively, the iron can derive nitrogen not only from the gases circulating in the cases, but also from the carbon employed.

At a recent meeting of the Academy, M. Boussingault stated, with an authority acquired by long observation in steel-works, that nitrogen always penetrates and circulates in the cementation cases, and consequently that it may nitrogenise the iron. Mr. Saunderson's important work, which I have already had occasion to cite several times before the Academy, also shows that cementation

is produced with difficulty except when nitrogen is present. M. Caron's observations on the rapid way in which steel is produced by cyanide of ammonium, and the formation of this body in cementation cases, prove equally that steel is, at the time of its production, in an ammoniacal and consequently nitrogenising atmosphere. The inference is that the gases and vapours circulating in the cases can nitrogenise iron.

I ought to inquire whether, apart from atmospheric nitrogen, the iron cannot also derive this element from the solid compounds found in cementation cases. I have ascertained that carbon itself may become a very active nitrogenising agent. The result of my experiments is that a nitrogenised organic matter when calcined leaves a carbonaceous residue, almost always containing nitrogen; exposed to the action of hydrogen it disengages abundance of ammonia. This production of ammonia cannot be attributed to the presence of cyanides in the residue, since the same result happens with an ash which has undergone washings in acids. Wood charcoal itself, after prolonged calcination at red heat, which gets rid of its alkalis and cyanides, still disengages ammonia under the action of hydrogen.

(To be continued.)

On the Application of Cyanide of Potassium in Soldering Metals, by Dr. AUGUST VOGEL.

In the operation of soldering metals, it is very essential to keep the metallic surfaces to be united clean and bright, so that the solder may adhere firmly when in a melted condition. For the purpose of protecting the metallic surfaces from the oxidising action of the atmosphere, certain fusible substances are usually rubbed on with the solder, and immediately form a thin layer over the surface of the metal. These substances produce, however, not only a protective, but also a reducing action. In practice it is sought to ensure these two essential conditions in the choice of the substances generally employed, viz., for soft soldering, resin, turpentine, olive oil, powdered sal-ammoniac, mixed either with oil, or with tallow and resin, or a very concentrated solution of chloride of zinc. For hard soldering borax, or a melted mixture prepared from borax, potash and common salt, and, in the special case of iron, pounded green glass is generally used.

It is well known that the substances above mentioned fulfil to a greater or less extent these two conditions of soldering, viz., deoxidation and protection of the metal from the atmosphere. A material possessing these two qualifications in the highest degree, would, of course, best effect this purpose. As the result of a great number of experiments, I have come to the conclusion that the ordinary commercial quality of cyanide of potassium possesses decided advantages in this respect over all other substances. It melts very readily, covering the surface of the metal with a very efficient protective layer, and at the same time is known to exert a strong reducing action, a property which has gained for it many important applications both in technical and analytical chemistry.

Cyanide of potassium will be found particularly useful when the surfaces to be soldered cannot be thoroughly brightened. It is difficult, and sometimes impossible, to solder metals when their surfaces are at all corroded, or when they are incapable of bearing the high temperature necessary in this operation, with the ordinary agents, on account of their inferior reducing power; but

cyanide of potassium, from its extraordinarily energetic action, is able to deoxidise all rusty particles standing in the way of the perfect union of the solder with the metal.

The mode of applying the cyanide of potassium in soldering is the same as with borax. Some powdered cyanide of potassium is kept ready at hand in a well-closed glass bottle; and sprinkled over the metallic surface after it has been slightly moistened. In some cases of soldering at very high temperatures, which, by practice, are soon ascertained, it will be found expedient to use a compound of borax and cyanide of potassium, for the purpose, on the one hand, of increasing, by this addition, the small reducing power of the borax, and, on the other hand, of diminishing the volatilising tendency of the cyanide of potassium.

Another reason for preferring the employment of this agent is, that during the operation no corrosive vapours capable of acting on the soldering tools are generated, as is the case with chloride of zinc.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, May 16, 1861.

Dr. A. W. HOFMANN, F.R.S., President, in the Chair.

Mr. PERKIN delivered the following discourse "*On the Colouring Matters, Derived from Coal-Tar.*"

The subject which I have the honour of bringing before you this evening is one which is remarkable for the very rapid progress it is making. Previous to the year 1856 the colouring matters derived from coal-tar products were practically unknown; but owing to recent discoveries they are now enumerated amongst the most important colouring matters employed. It is not my intention to enter into a discussion respecting the numerous patents that have been taken out for the production and application of coal-tar colours, nor yet to enter into the practical details of their manufacture; but to notice more particularly their various Chemical characters, and also to speak of the methods employed for their application to the arts. I shall endeavour to bring before you all the principal coloured products obtainable from the derivatives of coal-tar—both those which are practically employed by the dyer and printer, as well as those which still remain as chemical curiosities only. I may mention that the latter class of compounds is more extensive than the former, and also that many of the colouring matters in it are likely to remain so, for reasons to be mentioned presently.

The coal-tar products which have, up to the present, yielded colouring matters are numerous. The following is a list of the most important, which are obtained either directly or indirectly from coal-tar; namely, aniline and its homologues, carbolic acid, chinoline or quinoline, naphthalene, and pyrole bases.

I will commence by speaking of the first and most important of these products, and its derivatives,—namely, Aniline.

Aniline was discovered in 1826 by Unverdorben. The original method for its preparation was by digesting indigo with hydrate of potassium, and subjecting the resulting product to distillation. Aniline was also obtained from the basic oils of coal-tar; but the process which is now employed for its preparation is a remarkable instance of the manner in which abstract scientific research becomes, in the course of time, of the most important practical service. It was Faraday who first discovered benzole; he found it in oil-gas. After this it was

obtained by distilling benzoic acid with baryta, which result determined its formula, and was the cause of it being called *benzo's*. After this, Mansfield found it to exist in large quantities in common coal-tar naphtha, which is the source from which it is now obtained in very large quantities. Benzole, when studied in the laboratory, was found to yield, under the influence of nitric acid, nitro-benzole. Zinin afterwards discovered the remarkable reaction which sulphide of ammonium exerts upon nitro-benzole, converting it into aniline. And, lastly, Béchamp found that nitro-benzole was converted into aniline when submitted to the action of ferrous acetate. It is Béchamp's process which is now employed for the preparation of aniline by the ton. Had it not been for the investigations briefly cited above, the beautiful aniline colours now so extensively employed, would still remain unknown. When I discovered aniline purple, nitro-benzole and aniline were only to be met with in the laboratory; in fact, half-a-pound of aniline was then esteemed quite a treasure, and it was not until a great deal of time and money had been expended that I succeeded in obtaining this substance in large quantities, and at a price sufficiently low for commercial purposes.

The colouring matters obtainable from aniline are numerous. They are the following:—Aniline purple, violine, roseine, fuchsine, alpha aniline purple, bleu de Paris, nitroso-phenylene, dinitraniline, and nitro-phenylene diamine.

Aniline Purple, generally known as Tyrian Purple, Mauve, Phenamine, Indisine, &c.—It has been known for many years that the hypochlorites react on aniline and its salts, producing a purple-coloured solution; in fact, hypochlorites are the distinguishing test for aniline; but nothing definite was known of this purple-coloured solution, it being simply stated that aniline produced with hypochlorites a purple-coloured liquid, but that this colour was very fugitive. As many very absurd statements have been made respecting the discovery of aniline purple, I will just briefly mention how it was that I first became acquainted with it.

In the early part of 1856 I commenced an investigation on the artificial formation of quinine. To obtain this base I proposed to act on toluidine with iodide of allyle, so as to form allyle-toluidine which has the formula

thinking it not improbable that by oxidizing this I might obtain the desired result, thus—

Allyle-toluidine.

Quinine.

For this purpose I mixed the neutral sulphate of allyle-toluidine with bichromate of potassium; but instead of quinine I obtained a dirty reddish-brown precipitate. Nevertheless, being anxious to know more about this curious reaction, I proceeded to examine a more simple base under the same circumstances. For this purpose I selected aniline, and treated its sulphate with bichromate of potassium. This mixture produced nothing but a very unpromising black precipitate; but on investigating this precipitate I found it to contain the substance which is now, I may say, a commercial necessity, namely, aniline purple.

The method adopted for the preparation of aniline purple is as follows:—Solutions of equivalent proportions of sulphate of aniline and bichromate of potassium are mixed, and allowed to stand till the reaction is complete. The resulting black precipitate is then thrown on a filter and washed with water until free from sulphate of potassium. It is then dried. This dry product is afterwards digested several times with coal-tar naphtha until all resinous matter is separated, and the naphtha ceases to

be coloured brown. After this, it is repeatedly boiled with alcohol to extract the colouring matter. This alcoholic solution when distilled leaves the colouring matter in the bottom of the retort as a beautiful bronze coloured substance.

The aniline purple prepared according to the process just described, although suitable for practical purposes, is not chemically pure. If required pure it is best to boil it in a large quantity of water, then filter the resulting coloured solution, and precipitate the colouring matter from it by means of an alkali. The precipitate thus obtained should be collected on a filter, washed with water until free from alkali, and dried. When dry it is to be dissolved in absolute alcohol, the resulting solution filtered, and then evaporated to dryness over the water-bath. Thus obtained, aniline purple appears as a brittle substance, having a beautiful bronze coloured surface, but if some of its alcoholic solution be evaporated on a glass plate, and viewed by transmitted light, it appears a beautiful bluish violet colour. If considerable quantities of an alcoholic solution of the colouring matter, containing a little water be evaporated to dryness, the surface of the colouring matter next to the evaporating dish when detached, often possesses a golden green appearance. Aniline purple is difficultly soluble in cold water, although it imparts a deep purple colour to that liquid. It is more soluble in hot water, but its hot aqueous solution when left to cool assumes the form of a purple jelly. It is very soluble in alcohols, though nearly insoluble in ether and hydrocarbons. Aniline dissolves it readily. In properties it seems to be slightly basic, as it is more soluble in acidulated than in pure water. Alkalies and saline substances precipitate it from its aqueous solution as a dark purplish-black powder. Bichloride of mercury precipitates it in a very finely divided state. A little of this precipitate, which appears to be a double compound of chloride of mercury and colouring matter, when suspended in water and viewed by transmitted light, appears of a blue or violet colour. If a small quantity of hydrate of potassium or sodium be added to an alcoholic solution of the colouring matter, it causes it to assume a violet tint, but without effecting any change in the colouring matter itself. Ebullition with alcoholic potash does not decompose it. Aniline purple dissolves in concentrated sulphuric acid forming a dirty green solution. This when slightly diluted assumes a beautiful blue colour. Excess of water restores it to its original purple colour. I have had a specimen of this colouring matter heated for an hour to 100 Centigrade with Nordhausen sulphuric acid without suffering decomposition, being restored to its original colour by means of water, and possessing precisely the same properties as it had before being subjected to this powerful agent. Hydrochloric acid acts upon it in the same manner as sulphuric acid. It is decomposed by chlorine, and also by fuming nitric acid. Bichloride of tin is without action upon it. Powerful reducing agents have a peculiar action upon this colouring matter, somewhat analogous to the action of reducing agents on indigo. An alcoholic solution of sulphide of ammonium, when mixed with an alcoholic solution of the colouring matter, causes it to assume a pale slightly brownish colour. This solution when brought in contact with the atmosphere instantly assumes its beauty and intensity of colour. An alcoholic solution of the colouring matter when mixed with a little protoxide of iron changes to a pale brown colour. This solution also becomes purple when exposed to the action of the atmosphere. Sulphurous acid does not affect the colour of this substance.

This colouring matter forms a remarkable compound with tannin. When an aqueous solution of the colouring matter is mixed with a solution of tannin, precipitation takes place. The precipitate thus formed, after having been well washed, no longer possesses the properties of the pure colouring matter. It is insoluble in water. Like

the pure colouring matter it dissolves in concentrated sulphuric acid, forming a dirty green liquid; but on adding an excess of water to this solution the new compound is precipitated unchanged. This compound is rather duller in colour than the pure colouring matter itself. Aniline purple when agitated with a little moist binoxide of lead is transformed into roseine. This colouring matter is remarkable for its intensity, a few grains of it colouring a considerable quantity of spirits of wine.

Violine.—This colouring matter, which is a product of the oxidation of aniline, was first obtained by Dr. David Price. He prepares it by heating an aqueous liquid containing two equivalents of sulphuric acid, and one equivalent of aniline to the boiling point, and then adding one equivalent of binoxide of lead, boiling the mixture for some time and filtering it whilst hot. The filtrate, which is of a dark purple hue, is boiled with potash, both to separate the excess of aniline, and also to precipitate the colouring matter. When all the free aniline is volatilised, the residue is thrown on a filter and slightly washed with water, and then dissolved in a dilute solution of tartaric acid. This solution after filtration is evaporated to a small bulk, re-filtered, and then precipitated by means of an alkali. Thus obtained, violine presents itself as a blackish purple powder, which when dissolved in alcohol, and evaporated to dryness, appears as a brittle, bronze-coloured substance, similar to aniline purple, but possessing a more coppery-coloured reflection. It is more insoluble in water than the preceding colouring matter; it is very soluble in alcohol, but insoluble in ether and hydrocarbons. These solutions possess a colour somewhat similar to that of the field violet. Concentrated sulphuric acid dissolves it, forming a green solution, but excess of water restores it to its original colour. Like aniline purple, reducing agents deprive it of its colour, but which is restored by the action of the atmosphere. Tannin produces an insoluble compound with it, when agitated with a small quantity of binoxide of lead, it is converted into aniline purple; excess of this re-agent changes it into roseine.

Roseine.—This substance nearly always accompanies aniline purple, though in very small quantities. It was first noticed publicly, by C. Greville Williams, and afterwards by Dr. David Price. Williams used manganates for its preparation, but Dr. David Price prepared it by means of binoxide of lead. His process is as follows:—To a boiling solution of one equivalent of sulphate of aniline, two equivalents of binoxide of lead are added, and the mixture boiled for a short time. The rose-coloured solution is then filtered, and the filtrate evaporated to a small bulk, which causes a certain amount of resinous matter to be separated. This evaporated solution is then filtered, and the colouring matter precipitated by means of an alkali, it is then collected on a filter, slightly washed, and then dried. The colouring matter thus prepared, readily dissolves in alcohol, forming a fine crimson-coloured liquid, which when evaporated to dryness, leaves the colouring matter as a dark, brittle substance, having a slightly metallic reflection. It is much more soluble in water than either aniline purple or violine, but like them, it is insoluble in hydrocarbons, and is more soluble in acids than in neutral liquids. Concentrated sulphuric acid dissolves it, forming a green solution; excess of water restores it to its original colour. It forms a compound with tannin, and is also deodorised, or nearly so, by powerful reducing agents.

The three colouring matters just mentioned, namely, aniline purple, violine, and roseine are evidently closely allied, for they have nearly the same properties. They are all formed under similar circumstances, namely, by the action of oxidising agents in the presence of water; they are all slightly soluble in water, though as the shade of colour becomes redder, so their solubility increases; alkalis precipitate them from their aqueous solutions;

concentrated sulphuric acid dissolves them, forming green solutions which excess of water restores to the original colour of the colouring matters; powerful reducing agents deprive them of their colour or nearly so; but it is again restored by the influence of oxygen; and, lastly, tannin forms insoluble compounds with them all.

Fuchsine or Magenta.—This beautiful product, which is often improperly called rosine, is a member of an entirely different series of compounds from the foregoing, being formed under very different circumstances, and possessing very different properties. This colouring matter was first observed by Natanson, in 1856, when studying the action of chloride of ethylene on aniline, and afterwards, shortly before it was practically introduced into the arts, by Dr. Hofmann, when preparing cyantriphenyle-diamine by the action of bichloride of carbon on aniline. It was M. Verguin who first brought it forward as a dyeing agent, and who, I believe, taught manufacturers how to prepare it on the large scale. Fuchsine is invariably formed at a temperature ranging from 170 to 190 Centigrade. It is produced from aniline by the action of reducible chlorinized, brominized, iodized, or fluorized substances, as well as by weak oxidizing agents. The substances used for its preparation on the large scale are perchlorides of tin and of mercury, and the nitrates of mercury. It has also been prepared with bichloride of carbon.

Preparation of Fuchsine by the Action of Bichloride of Tin on Aniline.—Aniline combines with bichloride of tin, evidently producing a double compound. This product is a white substance, and may be prepared by adding to aniline, bichloride of tin in the anhydrous state or dissolved in water. Anhydrous bichloride of tin combines with aniline with great energy to form this compound. To prepare fuchsine from this double compound it is necessary that it should be free from water, or nearly so; therefore anhydrous bichloride of tin is generally employed for its preparation. The process adopted is as follows:—Anhydrous bichloride of tin is slowly added to an excess of aniline, the mixture being constantly stirred, and the pasty mass thus formed gradually heated. As the temperature increases it becomes quite liquid and also brown in colour. As soon as the temperature nearly approaches the boiling point of the mixture it rapidly changes to a black-looking liquid which when viewed in thin layers presents a rich crimson colour. This is kept at its boiling point some time, and then well boiled with a large quantity of water. By this means the principal part of the colouring matter is extracted together with considerable quantities of hydrochloride of aniline. The residue is a solid of brown colour and contains considerable quantities of tin in the form of a proto-compound. The aqueous solution of the colouring matter and hydrochlorate of aniline is then boiled, so as to volatilize any free aniline it may contain, and then saturated with chloride of sodium. The chloride of sodium causes the colouring matter to separate as a semi-solid, pitchy substance of a golden green aspect, while the hydrochlorate of aniline remains in solution. The colouring matter thus obtained may be further purified by digestion with benzole which dissolves out a certain amount of resinous matter.

Preparation of Fuchsine by the Action of Nitrate of Mercury on Aniline.—When protonitrate of mercury is left in contact with aniline for some time it forms a white pasty mass; but when carefully heated to 170° or 180° Centigrade it reacts upon it, forming a brown liquid, which gradually changes till of a dark crimson colour. At the same time, the whole of the metal of the mercury salt collects at the bottom of the vessel the experiment is conducted in. This product, when separated from the metallic mercury and allowed to cool, becomes semi-solid, being filled with crystals of nitrate of aniline. To purify this product it is best to dissolve out the nitrate of aniline it contains in a small quantity of cold water, and then to boil the remaining product several times with fresh

quantities of water until the principal of the colouring matter is extracted, and filter the resulting aqueous solutions while hot. On cooling the solutions will deposit the colouring matter as a golden-green tarry substance, from which benzole separates a small quantity of a brown impurity, leaving the colouring matter as a brittle solid.

I have briefly described the above processes because they may to some extent be regarded as types of most of the methods employed for the production of this colouring matter, the first representing its formation by the action of reducible chlorides upon aniline, and the latter by the influence of weak oxidising agents.

Fuchsine is undoubtedly an organic base, and a more powerful one than is generally supposed. The product obtained from aniline by means of bichloride of tin is hydrochlorate of fuchsine, and that obtained by the oxidising action of nitrate of mercury is the nitrate of fuchsine. My reason for stating this is, that on examining the colouring matter obtained by chloride of tin I found it to contain large quantities of combined hydrochloric acid, and when nitrate of mercury was used considerable quantities of combined nitric acid; therefore I conclude that the former is the hydrochlorate and the latter the nitrate.

Fuchsine is separated from its salts by precipitation with a small quantity of ammonia. When freshly precipitated, fuchsine is a red bulky paste which, when dry, contracts, forming a purplish red powder. It is difficultly soluble in water, though tolerably soluble in alcohol; it is not soluble in ether or hydrocarbons; a small quantity of hydrochloric acid causes it to dissolve freely in hot water, but an excess of either hydrochloric acid or sulphuric acid dissolves it, forming a brownish yellow liquid from which ammonia separates it unchanged. By this reaction it may be distinguished from rosine, which dissolves in strong sulphuric acid, producing a green liquid. Caustic alkalies, or ammonia in excess, partially precipitate fuchsine from its salts; but, at the same time, dissolve a considerable quantity of it, forming nearly colourless liquids. Acetic acid added to these alkaline solutions restores the colour of the fuchsine; and if the liquids are concentrated, the base precipitates as a red, flocculent substance. An alcoholic solution of fuchsine when evaporated to dryness, leaves the colouring matter as a brittle mass, having a remarkably beautiful golden green metallic reflection. By transmitted light it has a red colour. M. Béchamp has analysed carefully-prepared specimens of fuchsine, and found it to have the formula $C_{12}H_{12}N_2O$. This hydrochlorate he found to contain an amount of hydrochloric acid corresponding with the formula $C_{12}H_{12}N_2O, HCl$. He also examined the hydro-chloro-platinate, which is a purple precipitate; it has the formula $C_{12}H_{12}N_2O, HPtCl_3$. The existence of oxygen in this base is remarkable, because in many instances it is produced from agents which do not contain a trace of oxygen, as, for example, bichloride of tin and aniline. The only way I can account for the presence of oxygen in the product analysed is, that it was a hydrate; thus:—

This is, perhaps, to some extent confirmed by an experiment I made with iodaniline. I find that iodaniline, when heated, yields fuchsine. This change can only be expressed thus:—

But supposing the fuchsine examined by M. Béchamp to have been a hydrate, it is remarkable that its hydrochlorate and, more particularly, its hydro-chloro-platinate should also be hydrates. But as our knowledge of this

body is as yet but scanty, we must wait for the accumulation of facts before we can form any fixed opinion respecting its constitution. The compounds investigated by M. Béchamp appear to be uncrystallisable. Some time back, I had upward of 100 gallons of a hot aqueous solution of this colouring matter, which had been prepared by means of nitrate of mercury. This solution, on standing until cold, deposited a considerable quantity of colouring matter in the form of small octahedra, having a most beautiful green metallic reflection. Reducing agents decolorise fuchsine, but the oxygen of the atmosphere restores it to its original colour. If an alcoholic solution of fuchsine be left in contact with sulphide of ammonium until decolorised, or nearly so, and then exposed to the atmosphere, its colour is immediately restored; but if left to stand for several days and then subjected to the atmosphere, several hours elapse before it assumes its original colour. Like aniline purple, fuchsine is a very intense colouring matter. Tannin precipitates both fuchsine and its salts, forming difficultly soluble substances. Bichloride of mercury also precipitates this base and its salts, forming double compounds. When preparing fuchsine by means of bichloride of tin, or more particularly when using nitrate of mercury, there are two other colouring matters produced, one possessing an orange colour, and the other a purple hue. It is on account of the presence of the former that some samples of commercial fuchsine possess a scarlet character of colour. Of this orange colouring matter scarcely anything is known. It is not precipitated from these salts by means of alkalies. Of the purple colouring matter little also is known. It is formed at the same time as fuchsine, but in very small quantities, and from which it is difficult to separate perfectly. Its properties are similar to those of fuchsine. It dissolves in concentrated sulphuric acid, forming a reddish-brown solution, from which part of the colouring matter is separated by dilution with water. Hydrochloric acid dissolves it, forming a dirty yellowish-red liquid.

Bleu de Paris.—This is yet another colouring matter produced under circumstances similar to those which give rise to fuchsine. MM. Persoz, V. de Luynes, and Salvétat give the following account of its preparation and properties:—"9 grammes of bichloride of tin and 16 grammes of aniline, heated for 30 hours to a temperature of about 180 Centigrade, in a sealed tube, produce neither a red nor a violet, but a very pure and lively blue. This blue, which resists acids, darkens in colour by alkalies, but passes to a groselle violet when submitted to this agent in a concentrated state. It preserves its beauty of colour by artificial light, and it dyes animal fibres of a shade whose beauty leaves nothing to be desired." I repeated the above experiment twice, and was inclined to give up in despair, for instead of a fine blue I obtained nothing more than a dirty green product. But from this unpromising product I at last succeeded in obtaining this beautiful blue colouring matter, and found it to possess all the properties mentioned above. MM. Persoz, V. de Luynes, and Salvétat, have lately given a more particular account of this colouring matter. They describe it as crystallising from the alcoholic solution in the form of fine needles, having an aspect similar to that of ammoniacal sulphate of copper. It is soluble in water, alcohol, wood-spirit, and acetic acid; but insoluble in ether and bisulphide of carbon. With concentrated sulphuric acid it forms an amber-coloured solution which water converts into a magnificent blue liquid. Strong nitric acid decomposes it, chromic acid precipitates it from its aqueous solutions without decomposition; chlorine destroys it; sulphurous acid does not decolorise it. I found that sulphide of ammonium is also without action upon it. It is precipitated from its aqueous solutions by alkalies and saline compounds.

Aniline Green, or Emeraldine.—Most chemists who have worked with aniline in the laboratory must have noticed

the peculiar green coloured-substance which forms on the outside of the various species of chemical apparatus that have been standing in the vicinity of any quantity of this body. This product is aniline green. Aniline green has been known for several years. It may be formed by various processes. One process consists in oxidising aniline with chloric acid. This is effected by mixing a hydrochloric acid solution of aniline with chlorate of potassium. It may also be obtained by oxidising a salt of aniline with perchloride of iron. Obtained by either of these processes it presents itself as a dull green precipitate which, when dried, assumes an olive-green colour. It is insoluble in water, alcohol, ether and benzole; sulphuric acid dissolves it, forming a dirty purple-coloured solution from which it is precipitated unchanged by water. With alkaline solutions it changes to a deep colour somewhat similar to indigo; but acids restore it to its original colour. The colour of aniline green is much enlivened by the presence of an excess of acid; but, unfortunately, as soon as this acid is removed it passes back to its normal colour.

The bases toluidine, xylydine, and cumidine yield colouring matters under the influence of oxidising agents; and also when submitted to the action of reducible chlorides at high temperatures, analogous to those obtained from aniline under similar circumstances; but the results generally are not so good, the colour of the products becoming tinged with brown as the bases get higher in the series.

Nitroso-Phenylene.—This remarkable body is obtained by the action of nascent hydrogen on an alcoholic solution of di-nitro-benzole. It is represented by the formula $C_6H_5N_2O$. This body is almost insoluble in water, but soluble in acids, and in alcohol, producing crimson-coloured solutions, but its colour is not nearly so brilliant as that of fuchsine. It seems gradually to decompose when kept. I have not tried any experiment with it as regards its dyeing properties.

Dinitraniline.—Dinitraniline is obtained by decomposing dinitro-phenyle citraconamide by means of carbonate of sodium. When pure, it crystallizes in yellow tables. It dissolves very sparingly in water, producing a yellow liquid. It has the formula $C_6H_5(NO_2)_2$. It does not combine with acids or alkalies, although it appears to be more soluble in acidulated than in pure water. Silk can be dyed yellow with dinitraniline.

Nitrophenylene-diamine, or Nitrazophenylamine.—Dinitraniline, when submitted to the action of sulphide of ammonium, changes into this beautiful base, which crystallizes in needles of a red colour, somewhat similar in appearance to chromic acid. It dissolves in water, forming a yellow or orange-coloured solution like that of bichromate of potassium. Alcohol and ether dissolve it freely. It is not at all similar to fuchsine in its properties, as it forms salts of yellowish brown or grey colour; whereas fuchsine forms crimson ones. I mention this, because nitrophenylene-diamine has been spoken of as having properties similar to those of fuchsine. This base possesses the power of dyeing silk a very clear golden yellow colour.

Picric or Dinitrophenic Acid.—This beautiful acid was discovered as early as 1788, by Hausmann. It may be obtained by the action of heated nitric acid on a great variety of substances; the following are the names of some of them:—indigo, aniline, carboic acid, saligenine, salicylic and salicylic acids, salicin, phlorizin, cumarin, silk, aloes, and various gum resins. It is now prepared for commercial purposes from carboic acid, and also from certain gum resins. I have prepared it from carboic acid on the large scale, in the following manner, with success:—As strong nitric acid acts very violently when brought in contact with carboic acid, I have found it best to use an acid having a gravity less than 1.3, so as partially to convert the carboic acid, and afterwards to boil it in stronger

acid to change it into picric acid. On diluting the acid solution the impure picric acid precipitates. To further purify this it should be crystallized from boiling water. When preparing this product for commercial purposes it is advantageous to let all the nitrous fumes formed in its preparation, together with a certain amount of atmospheric air, to pass over a fresh quantity of carboic acid. This will absorb them, and at the same time be converted into nitro- or dinitrophenic acid, and consequently diminish the quantity of nitric acid required for its manufacture. When preparing picric acid from carboic acid there is always a quantity of a yellow, resinous matter produced, and at times a considerable quantity of oxalic acid. The latter is always produced when the acid which is used to finally convert the carboic acid is too weak, for then it rapidly decomposes the picric acid, yielding carbonic and oxalic acids. Picric acid, when pure and dry, is of a light primrose-yellow colour, crystallizing in strongly-shining lamina. It possesses an extremely bitter taste, and dissolves in water with a beautiful yellow colour. When digested with protoxide of iron in the cold it yields a brown amorphous compound, which dissolves in water with a blood-red colour. Picrate of copper is of a beautiful yellowish-green colour when in solution. If required for dyeing purposes, it may be prepared by mixing a solution of a picrate with sulphate of copper. Picric acid was introduced as a dye about five or six years since, by MM. Guinon, Marnas, and Bonney, eminent silk dyers of Lyons. Many of the cheap products sold as picric acid are of a brown colour, and consist of impure di- and tri-nitrophenic acids, and sometimes of this crude product and ground turmeric.

Rosolic Acid.—Runge first noticed this substance in 1834, when studying creosote, but it was almost lost sight of until again observed by Dr. Hugo Müller only a short time since. He accidentally observed that when crude phenate of calcium is exposed to a moist, heated atmosphere, as that of an ordinary drying stove, it gradually changes in colour, and assumes a dark red tint. This coloration is owing to the formation of rosolate of calcium. I have lately heard that phenate of sodium undergoes a similar change. Dr. Müller prepared rosolic acid from this product in the following manner:—The crude rosolate of calcium is first boiled with a solution of carbonate of ammonia. By this means a crimson solution containing the rosolic acid is obtained. This solution is then evaporated nearly to dryness, during which process ammonia is given off, and the crimson coloured liquid gradually changes to a yellowish red, and at the same time a dark resinous matter separates. This resinous substance is crude rosolic acid. In order to purify it it is submitted to the following treatment, proposed by Runge:—The crude rosolic acid is dissolved in alcohol, and hydrate of calcium added in slight excess. The beautiful crimson solution which is thus formed is agitated for some time with the undissolved portion of the lime, filtered, and the filtrate diluted with water, and, lastly, the alcohol distilled off. The residuary rosolate of calcium is then decomposed with just a sufficient quantity of acetic acid, and the whole boiled until every trace of free acetic acid and still adhering alcohol is volatilised. The rosolic acid separates first as a red precipitate, but when heated, cakes together, forming a dark, brittle substance, having a greenish metallic lustre.

It may be still further purified by solution in alcohol, to which a little hydrochloric acid has been added, and precipitation with water. Pure rosolic acid is a dark amorphous substance, possessing the greenish metallic lustre of cantharides. Its powder is of a red, or rather, scarlet shade, which, if rubbed with a hard, smooth body, assumes a bright gold-like lustre. In thin layers, rosolic acid presents an orange colour when viewed with transmitted light, but with reflected light a golden metallic appearance. When thrown down from an

alcoholic solution with water, it forms a flocculent precipitate of a bright red colour resembling the basic chromate of lead. Concentrated acids, as acetic, hydrochloric and sulphuric, readily dissolve rosolic acid, forming brownish yellow solutions from which water precipitates this acid unchanged. To cold water it imparts a bright yellow colour, and it is more soluble in hot than cold water. Alcohol and ether dissolve rosolic acid with great facility, forming orange or brownish yellow solutions which, on evaporation, leave it in an amorphous state. With ammonia, caustic alkalis, and caustic earths, it forms dark red compounds which dissolve with a magnificent red colour. These compounds are very unstable. No precipitates are formed with aqueous solutions of the rosolates, with the basic acetates of lead, or with any other metallic salt; nor is any carried down by alumina or any other metallic oxide. Dr. Müller made two combustions of rosolic acid, which yielded results that agree with the formula $C_{23}H_{23}O_4$. I and Mr. Duppa, when investigating some of the derivatives of acetic acid, found that when phenic and bromacetic acids were heated together at 120 Centigrade, two products were formed, one possessing all the properties of rosolic acid, while the other had the character of brunolic acid. We also found that a mixture of iodine and carbolic acid when heated with formic, acetic, butyric, or valerianic acids, produce rosolic acid, or a similar substance. A mixture of carbolic acid and iodine did not give a similar result; but a black solid, containing iodine. Rosolic acid has lately been prepared on a large scale, and employed for the purpose of printing muslins. I believe it was a rosolate of magnesium that was employed for this purpose. I do not think it is now used, having been replaced by the more beautiful colouring matter fuchaine. It was fixed by means of albumen.

The Colouring Matters of Quinoline or Chinoline.—Chinoline is found associated with lepidine, cryptidine, and other of the higher nitrile bases, in the basic oils obtained from coal tar, and also in the products obtained by distilling cinchonine with caustic alkalis. It was previously termed leucoline or quinoline; but the substance described under these two names was found to contain three or more distinct bases. These have been studied by C. Greville Williams, who has applied the name chinoline to the product which forms the principal part of the impure substance originally termed quinoline. The substance used for the production of colouring matters need not be pure chinoline, as that product originally termed quinoline is of sufficient purity for this purpose. Cinchonine appears to be the best source of chinoline, yielding, when distilled with excess of caustic alkali, 65 per cent. of this body sufficiently pure for manufacturing purposes. Chinoline yields three colouring matters—a violet, a blue, and a green. The following is an account of their preparation by C. Greville Williams:—

"In order to procure the blue colour, one part by weight of chinoline is to be boiled for ten minutes with one and a-half parts of iodide of amyl. The mixture from being straw-coloured becomes deep reddish brown, and solidifies on cooling to a mass of crystals. This product of the reaction is to be boiled for ten minutes with about six parts of water, and, when dissolved, filtered through paper. The filtered liquid is to be gently boiled in an enamelled iron pan over a small fire, and excess of ammonia gradually added. The ebullition may be prolonged with advantage for one hour, the evaporation of the liquid being compensated for by the gradual addition of weak solution of ammonia. The latter may be prepared by the admixture of equal volumes of ammonia of the density of 0.880 and distilled water. The hour having elapsed, the whole is allowed to cool, when the colour will almost entirely have precipitated, leaving the supernatant liquid nearly colourless. On pouring the fluid away (preferably through a filter, in order to retain floating particles of colour) the dish will be found to contain

resinous-looking masses, which dissolve readily in alcohol, yielding a rich purplish-blue solution, which may be filtered and kept for use.

"The colour prepared as above is, as has been said, of a purplish tint, but if a purer blue be required the following modification is to be resorted to. The filtered aqueous solution of hydriodate of amyle-chinoline, is as before, to be brought to the boiling temperature, but instead of adding ammonia, a solution of caustic potash containing about one-fifth of its weight of solid potash is to be substituted. The addition is to be continued at intervals until three-fourths as much potash has been added as is equivalent to the iodine in the iodide of amyle used. The fluid may, after a quarter of an hour's ebullition, be filtered to separate the resinous colour. The product is a gorgeous blue with scarcely any shade of red. On adding the other fourth of potash to the filtrate while gently boiling, a black mass will be precipitated containing all the red, which otherwise would have been mixed with the blue. This mass dissolves readily in alcohol, yielding a rich purple solution containing, however, an excess of red. The alcoholic solution on filtration leaves on the filter a dark mass soluble in benzole, and as sometimes prepared, affording a brilliant emerald green solution of great beauty. It is not always easy to obtain this green colour."

The properties of chinoline violet, and chinoline blue are, as far as I have been able to ascertain, identical. They are resinous substances which present a coppery appearance by reflected light; but when in very thin layers, appear of a violet or blue colour by transmitted light. They are bases, and dissolved in acids, forming pale red solutions, which ammonia restores to their original colours. They are slightly soluble in hot water. Tannin precipitates them from their aqueous solution, apparently forming an insoluble compound. Reducing agents do not affect their shade of colour.

Of chinoline green I know but little. Greville Williams describes it as having a brilliant emerald green colour of great beauty. I have observed that when chlorine is passed through an alcoholic solution of chinoline blue, it changes into a green; but whether this is the green spoken of by Williams, I am unable to state.

Naphthaline Colours.—The beautiful hydrocarbon, naphthaline, which has yielded such a long category of substances to the chemist,—up to the present time has yielded nothing of practical importance to the dyer. From it the following coloured derivatives have been obtained,—namely,—chloroxynaphthalic acid, perchloroxynaphthalic acid, carminaphtha, ninaphthalamine, nitrosanaphthaline, and naphthamein.

Chloroxynaphthalic and Perchloroxynaphthalic Acids.—These acids were discovered by Laurent. They are produced by digesting their chlorides, namely, the chloride of chloroxynaphthyle and the chloride of perchloroxynaphthyle, with an alcoholic solution of hydrate of potassium. They appear to be very difficult substances to obtain in quantity. I have not obtained satisfactory results when endeavouring to prepare them. They have the formula $C_{10}(H_5Cl)_2O_3$, and $C_{10}(HCl_2)_2O_3$, respectively. They are regarded with great interest as being very closely allied with alizarine, the colouring matter of madder; in fact, they are viewed as chloralizaric acid. That hypothesis is based upon the idea of alizarine having the formula $C_{10}H_4O_3$; but it happens very unfortunately for this theory, that the formula of alizarine itself is still a disputed point. Chloroxynaphthalic acid is of a yellow colour. It is insoluble in water, and difficultly soluble in boiling alcohol and ether; but it dissolves in concentrated sulphuric acid. This acid is a very sensitive test for alkalis, being changed to an orange red by them. This may be shown by moistening paper with a weak alcoholic solution of this acid, drying it, and then exposing it to

ammoniacal vapours. This will cause it to assume a red colour.

The chloroxynaphthalates are described as possessing great beauty, and are of yellow, orange, or crimson colours. The potassium salt is of a red crimson colour, and slightly soluble in water; the barium salt crystallizes in silky needles, having a golden reflection. The strontium, calcium, aluminum, and lead salts are of an orange colour; the cadmium salt is a vermillion-coloured precipitate; the copper and cobalt salts are crimson; and the mercury salt is of a red brown colour. I once dyed some silk with a small quantity of chloroxynaphthalate of ammonium, which I prepared, and found it to produce a good golden yellow colour, of great stability under the influence of light. Perchloroxynaphthalic acid is a yellow, crystalline body, insoluble in water, but soluble in alcohol and ether. With potash or ammonium it forms insoluble salts of red or crimson colour of great beauty.

Carminaphtha.—This colouring matter was also discovered by Laurent. It is obtained by heating naphthaline with a solution of bichromate of potassium, and then adding sulphuric or hydrochloric acid. It is described as a fine red substance, soluble in alkalies, but precipitated from its alkaline solutions by means of acids. I have never obtained this product when oxidizing naphthaline.

Ninaphthalamine.—Ninaphthalamine is a name which has been given to a remarkable base which was noticed by Laurent and Zinin; but nothing was known of its nature until subjected to investigation by Mr. Wood, who has both described and analysed it and some of its salts. Its formula is $C_{10}(H_2NO)_N$, or naphthalamine in which H is replaced by NO. Mr. Wood prepares this base in the following manner:—Sulphuretted hydrogen is to be passed through a boiling solution of dinitronaphthaline in weak alcoholic ammonia until nearly all the alcohol has distilled off, which operation should occupy two or three hours. The residue is then to be boiled with dilute sulphuric acid, and filtered. The filtrate, on cooling, deposits an impure sulphate of ninaphthalamine in the form of brownish crystals which are purified by recrystallization in water two or three times. I have found when crystallizing this salt that it is best to use water acidulated with sulphuric acid. When pure, this sulphate has to be decomposed with ammonia, and the resulting precipitate of ninaphthalamine washed with water. Thus obtained, ninaphthalamine appears as a bright red coloured crystalline precipitate, which when viewed under a lens appears as beautiful needles. It is very soluble in alcohol producing a solution which, when dilute, is of an orange colour slightly tinged with brown, not nearly so pure in colour as that of nitrophenylenediamine. It is slightly soluble in water, and possesses the power of dyeing silk with a colour somewhat similar to that of ordinary annata. With acids it produces colourless salts. Its formula is the same as that of nitroso-naphthaline, though it possesses very different properties. As a dyeing agent I do not think it would be of any value even if it could be obtained cheaply.

Nitroso-naphthaline.—This peculiar body is a product of the action of nitrous acid on naphthalamine. It is prepared by mixing a solution of hydrochlorate of naphthalamine with nitrate of potassium. From this mixture it separates as a reddish-brown precipitate. This, when washed with water on a filter and then dried, is dissolved in alcohol, filtered, and evaporated to dryness on the water-bath. Thus prepared, it is a crystalline, dark-coloured substance, having a greenish metallic reflection. It is soluble in alcohol, and also in benzole, forming orange red solutions. When acids are added to an alcoholic solution of nitroso-naphthaline it immediately assumes a most beautiful violet colour, as fine as any aniline purple. Alkalies restore it to its original colour. Silk may be dyed a beautiful purple shade with this substance, provided a certain quantity of hydrochloric acid or sulphuric acid be present. But what is most unfortunate

is, that when the silk thus dyed is rinsed in water the colour immediately passes back to that of the pure nitroso-naphthaline, and also that the amount of acid required to keep up the purple shade if left in the silk rots it in a few days. Could this purple be fixed, nitroso-naphthaline would be a cheap and most useful dye. I have endeavoured to produce the sulpho-acid of nitroso-naphthaline, thinking that if such a compound could be obtained, it would possess a purple colour because it would be an acid itself. But although sulphuric acid does dissolve it, forming a blue solution, yet no combination takes place. I also endeavoured to produce this desired result by treating sulpho-naphthalamine acid with nitrous acid, but obtained only nitroso-naphthaline, the acid of the sulpho-naphthalamine acid having apparently separated.

Naphthamein.—Piria observed that naphthalamine and its salts produced blue precipitates, afterwards becoming purple, when brought in contact with perchloride of iron, terchloride of gold, nitrate of silver, and other oxidizing agents. This product of oxidation he terms naphthamein. It is prepared by adding a solution of perchloride of iron to a solution of hydrochlorate of naphthamein. This mixture gradually changes and becomes blue, and after the lapse of a short time deposits a blue precipitate. This, when separated by means of a filter, is washed with water which causes it to change in colour until of a reddish-brown purple. The filtrate from this substance contains proto-chloride of iron, and, according to Piria, chloride of ammonium. Naphthamein when heated fuses and decomposes, leaving a residue of charcoal behind. It is insoluble in water, sparingly soluble in alcohol, but more soluble in ether. It forms a blue solution with concentrated sulphuric acid, and is reprecipitated from it by water. It dissolves in concentrated acetic acid with a purple colour, and is not precipitated from this solution by means of water. Silk and cotton may be dyed with it, but the colour of this compound is so inferior as to render it useless as a dyeing agent.

Tar Red.—This colouring matter was discovered by Mr. Clift, of Manchester, in 1853. It is obtained by exposing a mixture of the more volatile parts of the basic oils of coal-tar and hypochlorite of calcium to the air for about three weeks. Of the pure colouring matter I know nothing, except that with tannin it forms an insoluble, or difficultly soluble, substance. With different mordants it yields different colours. It seems probable that this colouring matter is derived from pyrrole.

Azuline.—This substance, which is a beautiful blue dye, has been introduced within the last six months. It was discovered by MM. Guinon, Marnas, and Bonney, of Lyons, who keep the process for its preparation a secret. It is obtained from coal-tar, but from which of its numerous derivatives is not known. This colouring matter is a brittle, uncrystallizable body, possessing a coppery metallic reflection. It is very difficultly soluble in water, but soluble in alcohol, producing a magnificent blue solution, having but a slight tinge of red. With concentrated sulphuric acid it forms a blood-red liquid which, when poured into an excess of water, precipitates the colouring matter unchanged. Dilute acids have no effect upon azuline. Its alcoholic solution, when mixed with an alcoholic solution of hydrate of potassium, also changes to a dull red colour. This, when diluted with water, forms a purple liquid which is gradually restored to its original blue colour by hydrochloric acid. With excess of ammonia the solutions of azuline change to a reddish purple colour. This ammoniacal solution, when treated with sulphide of ammonium gradually assumes a dull, yellowish-brown colour. Iodine destroys the colour of azuline. In colour it is not quite so fine as chinoline blue, though far superior to Prussian blue.

Application of Coal-tar Colours to the Arts of Dyeing and Calico Printing.—I cannot enter fully into this subject, because not being a practical dyer or printer, I do not feel

sufficiently acquainted with the various operations of the dye-house or print-works to do so, and also because the technical details of dyeing and printing operations would not, I think, interest the Society. I therefore propose to speak of the different processes employed for dyeing and printing with coal-tar colours, in general terms only.

Dyeing Silk and Wool.—Silk and wool can be dyed with all the coal-tar colours with the exception of the rosolates, these fibres possessing, in most cases, a remarkable affinity, if I may so speak, for these colouring matters. Many of them, as aniline purple and violine are taken from their aqueous solutions so perfectly by these substances that the water in which they have been dissolved is left colourless; in fact, silk and wool take them up so rapidly that one of the great difficulties the dyer has to contend with is to get the fibres dyed evenly.

To Dye Silk with Aniline, Purple, Violine, and Rosoline.—One process is applicable for dyeing silk with either of these colouring matters, and it is a very simple one. An alcoholic solution of the colouring matter required is to be mixed with about eight times its bulk of hot water previously acidulated with tartaric acid, and then poured into the dye-bath, which consists of cold water slightly acidulated. After being well mixed, the silk is to be worked in it until of the required shade. If a bluer shade than that of the colouring matter is required, a little solution of sulpho-indigotic acid may be added to the dye-bath, or the silk may previously be dyed blue with Prussian blue, or any other blue, and then worked in the dye-bath.

To Dye Silk with Fuchrine, Picric Acid, Chinoline Blue, and Chinoline Violet.—This process is still more simple than the above, as it is simply necessary to work the silk in cold, aqueous solutions of these colouring matters. With fuchrine or picric acid a little acetic acid may be used, but with chinoline colours acids must be avoided. With picric acid a very clear green colour may be obtained by adding a little sulpho-indigotic acid to the dye-bath. I may mention that violine is not of such a fine colour as that produced by aniline purple and indigo blue; and also that rosine is not such a good colour as fuchrine or magenta.

To Dye Silk with Aniline.—The dyeing of silk with this colouring matter is far more difficult than with the preceding, requiring to go through two or three different processes. This difficulty, I believe, arises from the insolubility of aniline in water. The process generally employed is to work the silk in a solution of the colouring matter acidulated with sulphuric acid, and when of a sufficient depth, to raise the temperature of the dye bath to the boiling point, and work the silk in it again. After this the silk is well rinsed in water until free from acid, and worked in a bath of soap lather. It is then again rinsed and finished in a dilute acid bath.

To Dye Wool with Aniline Purple, Violine, Rosoline, Fuchrine, and Chinoline Colours.—This operation is generally conducted at a temperature of 50 or 60 Centigrade, and the dye-bath is composed of nothing but a dilute aqueous solution of the colouring matter required. Acids should be avoided, or only a very small quantity used, as the resulting colours are not so fine when they are employed.

Methods of Dyeing Cotton with Coal-Tar Colours.—When aniline purple was first introduced, considerable difficulty was experienced in dyeing cotton so as to obtain a colour that would resist the action of soap. Aniline purple is absorbed by vegetable fibres to a certain extent, and very beautiful colours may be obtained by simply working cotton in its aqueous solution; but when thus dyed the colours will not stand the action of soap. I have tried the use of tin and other mordants, but without any satisfactory result.

In 1857, Mr. Fuller, of Perth, and myself simultaneously discovered a process by which this colouring matter could be fixed upon vegetable fibres so as to resist the action of

soap. This process is based upon the formation of an insoluble compound of the colouring matter with tannin and a metallic base in the fibre. To effect this the cotton has to be soaked in a decoction of sumac, galls, or any other substance rich in tannin, for an hour or two, and then passed into a weak solution of stannate of sodium, and worked in it for about an hour. It is then wrung out, turned in a dilute acid liquor, and then rinsed in water. Cotton thus prepared is of a pale yellow colour, and has a remarkable power of combining with aniline purple.

The above process may be modified: for example, the stannate of sodium may be applied to the cotton before the tannin, and alum may also be used in the place of stannate of sodium. To dye this prepared cotton with aniline purple it is only necessary to work it in an acidulated solution of the colouring matter; and when thus prepared the cotton will absorb all the colouring matter of the dye-bath, leaving the water perfectly colourless. It has been found that cotton thus prepared can be dyed with any colouring matter that forms insoluble compounds with tannin; therefore it is used for dyeing with rosine, violine, fuchrine, and chinoline colours.

Cotton may also be dyed a very good and fast colour by mordanting it with a basic lead salt and then working it in hot solution of soap to which aniline purple has been added. Oiled cotton, such as is used for dyeing with madder, is also used in dyeing these colours. Cotton simply oiled, and before mordanted with alum and galls, also combines readily with these colouring matters; but as the colour of the prepared cotton is generally rather yellow, it interferes sometimes with the beauty of the result. Cotton is sometimes coated with albumen, which is coagulated by the action of steam, and the albumen which covers the cotton dyed in the usual manner. I may mention that violine, rosine, fuchrine, and also the chinoline colours combine with unmordanted vegetable fibres, as well as aniline purple. Picric and rosolic acids are not applicable for dyeing cotton.

Printing Calico with Coal Tar Colours.—The process generally employed for printing with these colouring matters is simply to mix the colouring matters with albumen or lacterine, print the mixture on the fibre, and then to coagulate the albumen or lacterine by the agency of steam. I and Mr. Gray, of the Dalmonach Print Works, discovered the first process of applying these substances to fabrics in a different manner to the above. It consisted in forming a basic carbonate or an oxide of lead on those parts of the cloth which were to be coloured, and then working the cloth thus prepared in a hot lather containing the colouring matter. Where the cloth was mordanted with the lead compound colouring matter was absorbed; but when unmordanted it was left white, because pure cotton is not dyed with these colouring matters in the presence of soap. This process was intended for the application of aniline purple, for at the period of this discovery the other coal tar colours were unknown. Colours dyed by this process were very pure, but it had many disadvantages, which have caused it to be disused. Lately the process previously described for dyeing colours upon cotton prepared with tannin has been applied to calico printing. It consists in printing tannin upon the fabric previously prepared with stannate of sodium, and then dyeing it in a hot dilute acid solution of the colouring matter. By this means the parts of the fabric which are covered with tannin are dyed a deep colour, but the other parts are only slightly coloured. These are cleared by means of well-known processes. This method of applying these colouring matters is also modified by printing a compound of the colouring matter required and tannin on the prepared cloth, instead of tannin only, and then steaming the goods.

Method of Applying Aniline Green to Fabrics.—This process is interesting as being the first example of the production of coal-tar colours on the fabric itself. It was

proposed by Professor Calvert. His process is very simple. The design is to be printed on the cloth with a thickened solution of chlorate of potassium, dried, passed through a solution of an aniline salt, again dried, and allowed to hang in a moist atmosphere. In the course of two or three days the colour will be fully developed. The colour thus produced may be changed into a dark blue by the agency of soap or an alkaline liquid. This process is very inexpensive, the amount of aniline required being very small.

Application of Nitrosonaphthaline.—If cloth is printed with a thickened solution of a salt of naphthalamine, dried, and then passed through a solution of nitrite of potassium, nitrosonaphthaline will rapidly make its appearance as a reddish orange colour; but, unfortunately, the colour thus obtained will not resist the action of soap well.

Of the numerous colouring matters of which I have briefly spoken, there are only four that are at present employed by the dyer and printer, namely, aniline purple, fuchsine, picric acid, and azuline; but I think it probable that others of them will soon be introduced, such as the *bleu de Paris*; and nitrophenylene diamine might be used for silk dyeing, as its colour is good and it stands the action of light well. Unfortunately, the chinoline colours, though very beautiful, are most fugitive. There has been an endeavour to introduce the chinoline blue of late, but although a considerable quantity of silk was dyed with it at first, it is now scarcely used, because when exposed to the sun for two or three hours the dyed silk becomes bleached. Aniline purple resists the light best. Fuchsine and alpha aniline purple soon fade, especially when on cotton. Azuline and *bleu de Paris* are not easily acted upon by light when on silk.

When the colouring matters of coal-tar were first introduced, there was a great fear that the workmen engaged in their manufacture, would suffer in health. All I can say is, that during the few years I have had to do with this branch of manufacture, there has not been a single case of illness among the workmen that has been produced by any operations carried on for the production of aniline purple.

The CHAIRMAN: Gentlemen, I am sure I am only expressing the opinion of the Society in conveying to Mr. Perkin the best thanks of the meeting for the important and remarkably illustrated Lecture which we have just heard. The great interest which this subject has excited is amply testified by the large audience which it has collected together, anxious to hear an account of the development of an industry in the carrying out of which Mr. Perkin has been particularly instrumental. As far as I am myself concerned, I must say that I have listened to this Lecture with the greatest interest, and with particular gratification. Having had the good fortune of guiding the early researches of Mr. Perkin, I cannot but feel the most lively interest in the success of this great industrial achievement which Mr. Perkin has accomplished. The courage and the perseverance with which he has gone on in his experiments must be appreciated by everyone familiar with the great many difficulties which beset the path of an inventor. These difficulties I know have not failed in the case of Mr. Perkin, and he deserves infinite credit, that whilst engaged in carrying out commercial undertakings of very considerable magnitude, he has found time to devote his attention to investigations of purely scientific interest—investigations which have occupied the attention of this Society repeatedly during the last few years. There is another cause from which I have derived great gratification in listening to these Lectures. This is of a mere personal character, and I will allude to it only in the most general terms. We all return with very great satisfaction and delight to our first loves. I must confess that aniline was one of my early flames—(laughter)—and I feel great pleasure in seeing it so popular in these times. I see before me quite an array

of distinguished members of the Chemical Society, and more especially the very father of this whole industry—Mr. Faraday, the discoverer of benzole. (Applause.) Perhaps he will kindly favour us with some remarks.

Professor FARADAY: What an encouragement it affords, sir, to the young chemist to pursue his studies earnestly and heartily, when he finds that such a small thing as the separation of benzole from other matters may lead to such large results!

The CHAIRMAN: The meeting is honoured by the presence of another gentleman whose remarks the Society have always heard with the greatest pleasure and delight,—Professor Playfair, of Edinburgh, is with us this evening.

Professor PLAYFAIR: Your commands, Mr. President, are imperative from the chair, but I have exceedingly little to say, except to repeat the gratification which, with you, I entertain, and also to express the feelings which one must share when we consider that the parent of these discoveries has produced from his first love such an array of children, to whom, as parent is apt, he has given such long and wonderful names—(laughter),—they producing in their turn a progeny of great beauty with most blooming colours and with the promise of numerous descendants with much more elegant names, such as fuchsine and roseine, and which are much more likely to carry down his fame to posterity. I am speaking seriously in this, for I believe and I have heard in some manufacturing districts when speaking with several calico-printers, that they look upon this discovery—to which Mr. Perkin has added so much—as very great in a national point of view. I have heard some who are well informed upon the subject, and well qualified to judge of it in this point of view, say that the progress making with regard to these colours from coal-tar was so great, and the practical discoveries for applying them to industry are becoming so simplified, that they are of opinion that in a few years instead of our being a colour-importing nation—instead of depending upon Turkey and Holland for madders,—by producing a staple colour of our own, we shall in all probability become the great colour-exporting nation of the world. I therefore think that Mr. Perkin whom Dr. Hofmann, in his sagacity and his care for these beautiful children of his, employed early and trained to be a nurse to rear them in the admirable way in which he has done, will be exceedingly gratified in finding that he has founded a national industry; and in the Exhibition of 1862, I hope Mr. Perkin will take care that the world shall see what has been done in the last few years in this branch of science, and that he will give us a full illustration of these beautiful discoveries.

ROYAL INSTITUTION OF GREAT BRITAIN.

Weekly Evening Meeting, Friday, March 15, 1861.

*A Lecture on Electrical Quantity and Intensity,
by LATIMER CLARK, Esq.*

THE modifications of the strength of the electric current in dynamic electricity, and in the amount of charge in static electricity, are at present usually defined by the terms Quantity and Intensity. The speaker pointed out that the expression intensity, as ordinarily understood, really involved two perfectly distinct qualities, and dwelt on the advantage which would accrue to electrical science by the habitual separation of the complex idea of intensity into its two component parts, viz. that of tension, as propounded by Ohm in his celebrated mathematical investigation of the galvanic circuit; and that of quantity, as developed by Faraday in those valuable researches in which he established the definite quantitative character of electrochemical decomposition and the action of electricity on the galvanometer. The term "tension," as here used, is

intended to convey the same idea as the expression electromotive force, or as the term "electric potential," employed by Green and other mathematicians, and is entirely dissociated from the idea of quantity; both terms are equally applicable to electricity at rest or in motion.

The quantity of electricity, both in its static condition and in its motion through conductors, usually varies directly as the tension, and hence their joint effects have been ordinarily confounded together and attributed to one cause under the name of intensity; but since the tension and quantity do not, under all circumstances, vary in the same ratio, there exists an absolute necessity for their clear separation before any numerical reasoning can be founded on them. Cases of the independent variation of tension and quantity were shown, and it was pointed out that all the most striking properties of electricity, such as the decomposition of water and salts, the combustion of metals the deflection of the galvanometer, the attraction of the electro-magnet, and the physiological effects of the current were really dependent as regards their magnitude and energy, solely on the quantity of electricity passing. Their greater energy when the tension was increased, was an indirect effect, due not to that tension, but to the increased quantity which passed in a given time by reason of the increased tension. A galvanometer wound with a few turns of thick wire was shown to be deflected as powerfully by one cell as by six, or even by 600 cells of the same size, because by reason of its shortness the wire conveyed freely the whole quantity which one cell could produce, which was the same as that produced by the whole 600; but any alteration in the size of the cell produced a consequent change in the quantity and in the deflection of the galvanometer. On the other hand, a galvanometer with many thousand turns of fine wire gave the same deflection with a battery formed of a small gun-cap, as with one of twenty square feet of surface, because the quantity in this case was regulated and limited not by the size of the plates, but by the power of conduction of the wire; the quantity being therefore the same in both cases. In every case the deflection was dependent solely on the quantity of electricity actually passing through the instrument without reference to its tension.

The combustion of metals was shown to be a phenomenon dependent on quantity, and not on tension; one cell of Grove's battery ignited a certain length of platina wire; and whatever its size it would ignite no greater length; but two, three, or more cells were shown to ignite two and three times the original length, the quantity passing in the greater length being under the higher tension, precisely the same as in the original length. This explained Faraday's oft misunderstood remark, that the same quantity of electricity which would ignite an inch of wire, would ignite a foot or a mile.

The pain and shock experienced on touching a powerful battery, or shocking coil, or Leyden jar, were proportionate to the quantity of electricity passing through the system, and not to the tension. A carrier ball or minute Leyden jar charged to the highest tension, would produce no sensation if the quantity were absent, and the same was the case with a Zamboni's pile. Sparks nearly eighteen inches long were received from an electrical machine; but although of this high tension, they produced no violent physiological effects, owing to their deficiency in quantity. Long sparks, nevertheless, produced greater effects than short ones because at double the striking distance the tension is doubled, and the quantity is therefore twice as great. The quantity contained in a Leyden jar or battery is comparatively great, and the effect on the system proportionately violent. Two conditions were necessary for these effects: first, that the quantity present should be considerable; and secondly, that the tension should be sufficiently great to make it pass through the system. A battery of two or three cells, which could readily fuse platina wire, was shown to produce no painful sensation

on the tongue, because, although the quantity was abundant the tension was low; while another battery of 600 cells, which produced the most intolerable shock to the system had, from its deficiency in quantity, scarcely any power to fuse wire. The Ruhmkorff coil combined very high tension with considerable quantity, and its physiological effects were therefore very violent.

A frictional machine was exhibited by Mr. Varley, constructed on a plan of Dr. Winter's; the plate was of vulcanite, or vulcanized Indian-rubber, about three feet in diameter, excited by amalgam in the usual way; its peculiarity was a large and lofty wooden ring, with a metallic rod in its interior, which, by its overshadowing inductive influence, increased the length of the sparks from six or seven inches to nearly eighteen.

The forces of electrical attraction and repulsion are sometimes stated to vary as the square of the intensity, sometimes as the square of the quantity, and sometimes as the square of the distance; but it was contended that these effects were due to the circumstance that the quantity usually varies in the same ratio as the tension, and as the distance; and that all the phenomena were more rationally explained by the assumption that electrical attraction and repulsion vary in the simple ratio of the quantity and of the tension, and of the distance inversely.

(To be continued.)

CORRESPONDENCE.

On the Adulteration of Food.

To the Editor of the CHEMICAL NEWS.

SIR,—In the discussion of this question the mustard trade has been so often alluded to, as one in which adulteration is carried to its greatest extent, that it becomes a matter of importance to know how far the statements that have from time to time been put forward are correct, and to ascertain what changes we may expect to bring about in supplies of this article by means of legal enactments; for since this trade appears to be so generally acknowledged as most fully exemplifying the evils of adulteration, we may, by investigating this particular branch of manufacture, arrive at some conclusion as to how far we may hope to protect ourselves against the adulteration of articles of food by passing more stringent prohibitory regulations, and how much must still be left to the exercise, on the part of the public, of discretion and common sense. I have, therefore, endeavoured to collect information from various sources on this subject, and have considered that a short detail of the results of my inquiries may not be uninteresting to your readers.

Mustard-seed is of two kinds, brown and white, a mixture of the flour of both kinds being generally used in all qualities of mustard. The flour from the brown seed possesses the greatest pungency, whilst that from the white seed has a finer appearance and more delicate flavour. The seed is crushed by steel rollers, then pounded in iron mortars, and the flour separated from the bran by sieves. On account of its oily nature, the seed is not readily reduced to powder, but requires careful crushing, the operation being repeated several times. The flour which passes through the finest sieves after the first grinding is sold as "D.S.F." (double superfine), and is worth, wholesale, from 1s. 3d. to 1s. 9d. per lb. The coarser flour is again ground with a little corn flour and cayenne, and sold as "S.F." (superfine). The product of a third grinding is mixed with more corn flour, cayenne, and a little turmeric, and is sold as "fine;" whilst the produce of a still further grinding of the coarse particles is again mixed with corn flour, cayenne, and turmeric, and sold as "seconds."

Admixture of mustard with flour, capsaicums, or other spice, and turmeric as a colouring material is in general use by the first manufacturers, and no pretence is made of concealing the fact.

Apart from the object of lowering price, admixture is resorted to in order to suit the taste of customers, and to render the mustard capable of being kept for a longer period. There is every reason to believe that the use of plaster of Paris is not uncommon, though this practice is not resorted to by the more respectable houses. The manufacturer is just as ready to sell genuine mustard as he is the mixed qualities, provided he can obtain a corresponding price, but it is impossible he can do this whilst "best mustard" is sold at 11d. or 1s. per lb., whereas the genuine would cost from 1s. 3d. to 1s. 9d. per lb. So long as the public will buy mustard at present prices, the manufacturer is obliged to resort to admixture. If the agent of a manufacturer offer to the retail tradesman a genuine article, he is told, that "We buy at twenty per cent. below yours; we don't know how it is made, but our customers make no complaints, and it answers our purpose. When you have an article to offer at our price, we can do business with you." Or, even supposing that the manufacturer has managed to obtain a demand for a genuine article, he knows very well, unless he will supply all qualities, his returns will not pay his traveller's expenses. The manufacturer is thus compelled to follow in the track of others, and so long as he abstains from using any pernicious ingredient, and selling a mixed article as genuine, I cannot see that any portion of the blame can rest with him. The prohibition of the sale of any but a genuine mustard would not be likely to meet with the approval of the public, inasmuch as, since the coarser qualities could scarcely be made into a marketable article, the price of mustard would be raised to an enormous extent, and the poorer classes would find themselves, in a great measure, deprived of a cheap and agreeable condiment. The question of the purity of mustard appears to me to rest principally with the consumer. So long as the public insist upon being supplied at a price below that at which the genuine can be sold, so long will adulteration be resorted to. Create a demand for the genuine article at a remunerative price, and there is no difficulty in obtaining a supply. It would, indeed, be a matter of surprise if a sample of mustard, sold retail at three farthings per oz., should be found to be genuine, and the only use of analysis of such samples is to show the nature of the adulterating material employed. I think it must be manifest to all who fairly consider this question of adulteration that all which legislation can do is to make the admixture of any substance acknowledged to be pernicious or deleterious to health with articles of food, and the selling of an adulterated article as "genuine," punishable by fines and penalties, on conviction of the offending parties before a magistrate.—I am, &c. VERAX.

On Naphthalic Alizarine.

To the Editor of the CHEMICAL NEWS.

SIR,—Observing in your last impression a notice (from the *Comptes-Rendus*) of M. Roussin's note on the artificial production of alisonine, I wish here to record that more than five years ago my researches upon naphthaline and some of its derivatives led me somewhat in the direction of the colour I endeavoured to produce; and early in 1857 I obtained, by a process differing only in detail from that of M. Roussin, a fine red colour, approaching the one sought. I showed some of the crude product, in the same year, to my friend Dr. B. W. Richardson, who expressed his opinion that the product in question very greatly resembled alizarine, if it was not identical with that principle. Circumstances unnecessary to publish, but which I explain herewith for your personal satisfaction

only, prevented my continuing the investigation until a few weeks ago.

I need scarcely say that the preceding remarks are not intended to be taken as in any way antagonistic to the perfectly independent experiments of M. Roussin or others (which indeed they tend rather to corroborate), but are penned in simple justice to myself.—I am, &c.

WENTWORTH L. SCOTT.

Bayswater, June 3, 1861.

Dead Black for Metal Work.

To the Editor of the CHEMICAL NEWS.

SIR,—In reply to your correspondent's enquiry relative to the most suitable dead black varnish for coating the sights of rifles, I would recommend a trial of the material ordinarily used 'by foundry' pattern-makers for staining the wooden model black, and rendering it less impervious to moisture before proceeding to make the sand mould. This varnish is easily prepared, by incorporating lamp black with a solution of shellac in methylated spirit. Applied to the metal surface with a camel's-hair pencil, it quickly dries to a dead black surface, firmly adherent, not sensibly affected by rain, and so simple of application, that should it happen to become rubbed off, it may easily be renewed.—I am, &c.

ANOTHER RIFLEMAN.

MISCELLANEOUS.

Royal Institution of Great Britain.—At the General Monthly Meeting, held on Monday, June 3, 1861, Rev. John Barlow, M.A., F.R.S., in the chair, the Secretary announced that his Grace the President had appointed the following Vice-Presidents for the ensuing year:—the Lord Wensleydale, the Lord Stanley, M.P., F.R.S., Sir Henry Holland, Bart., D.C.L., D.D., F.R.S., the Rev. John Barlow, M.A., F.R.S., John Peter Gassiot, Esq., F.R.S., and William Pole, Esq., F.R.S., the Treasurer. Frederick Augustus Burgett, Esq., John Dobie, Esq., Henry Wells Foote, Esq., William W. Gull, M.D., John Philip Malleon, Esq., B.A., and John Wells Wainwright, M.D., were elected Members of the Royal Institution. H. A. Pitman, Esq., was admitted a Member of the Royal Institution. The presents received since the last meeting were laid on the table, and the thanks of the Members returned for the same.

ANSWERS TO CORRESPONDENTS.

* In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

* All Editorial Communications are to be addressed to Mr. CROOKES, and Advertisements and Business Communications to the PUBLISHERS, GRIFFIN, BORN & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

Vol. II. of the CHEMICAL NEWS, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1861, and will be complete in 26 numbers.

A Subscriber.—1. Professor Way, Welbeck Street. 2. Messrs. Johnson and Matthey, Hatton Garden.

Electro-Plating Solution.—H. Wake.—Dissolve one ounce of fine silver in nitric acid, add three pints of water, and precipitate with common salt. Wash well, and dissolve the chloride in just enough cyanide of potassium to effect solution; filter and add water to one gallon. If the articles are required to come out bright, instead of dull, add a little bisulphuretted carbon to the solution.

P. M. H.—Received.

VOL. III. No. 80.—June 15, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On a Fifth Element belonging to the Alkali Group, by Professor BUNSEN.

IN the investigation of the new metal having so close an affinity to potassium, and which has been called *cæsium* by Bunsen, there appears to exist, besides this *cæsium*, yet a fifth alkali metal, which has hitherto escaped notice, and which appears to resemble potassium quite as much as *cæsium* does.

The platinum salt of *cæsium* is with much more difficulty soluble in water than that of potassium. If we attempt to separate the latter from the former by repeated boiling with water, we find that in proportion as the quantity of potassium diminishes, and the continuous potassium spectrum between $K\alpha$ and $K\beta$ becomes faint, new lines appear, and among these in particular two very intense ones in the violet between $Sr\delta$ and $K\alpha\beta$. A point is soon reached at which the quantity of potassium is no longer diminished by boiling with water. This occurs when the united atomic weight of the metals combined with chlorine and platinum is 109 ($H = 1$). If, now, a mixture of the hydrates of potassium and *cæsium* be prepared from the platinum compounds, and about a fifth of this mixture be converted into carbonate, then absolute alcohol will abstract from the dried mixture almost exclusively hydrate of *cæsium*. If this operation be repeated, a limit is at length reached at which that which is dissolved in the alcohol has a constant composition. This occurs when the atomic weight has risen from 109 to 123.4 ($H = 1$). The substance which possesses this enormous atomic weight (next to gold and iodine, the greatest known) forms a deliquescent hydrate, as caustic as hydrate of potassium; it forms an equally deliquescent carbonate, which, at ordinary temperatures, is soluble to the extent of 10 parts in 100 of absolute alcohol; and an anhydrous nitrate, which crystallises, not rhombic, like nitre, but hexagonally, and by a hemiedral form, is isomorphous with nitrate of sodium, &c. The spectrum of this substance, purified up to an atomic weight of 123.4, shows the blue *cæsium* lines with great intensity, but the violet lines of the unpurified substances (atomic weight 109) so faintly, that a slight addition of chloride of potassium, which scarcely affects the lines $Cs\alpha$, makes them disappear at once, on account of the brightness of the ground produced by the potassium. The few grammes of material for this investigation were obtained from 44,000 kilogrammes of the Dürkheim mineral water. By a repetition of the process, from 150 kilogrammes of Saxon lepidolite, there was obtained by the first treatment with chloride of platinum, a product which exhibited the violet lines between $Sr\delta$ and $K\alpha\beta$ with the utmost intensity, but no traces of the lines $Cs\alpha$. If this platinum salt from lepidolite had been a mixture of the

cæsium and potassium compounds, the blue lines $Cs\alpha$ must have been visible along with the violet ones, because in the product obtained from the Dürkheim water, the violet lines disappear, first on the addition of chloride of potassium, and the *cæsium* lines much later, and, indeed, only when the potassium salt is in very great excess. It follows that there must exist, besides, potassium, sodium, lithium, and *cæsium*, yet a fifth alkali metal, which occurs in Dürkheim, Kreusnach, and other mineral springs, in small, but in lepidolite in larger quantities.—*Bericht der Akad. der Wissensch. zu Berlin*, 1861, S. 273—275.

On the Expansion of Metals and Alloys, by F. CRACE CALVERT, Ph.D., F.R.S., F.C.S., &c., R. JOHNSON F.C.S., and G. CLIFF LOWE.

Cu = 93.17	—	—	—	—	—	—	—	—	—	—

The results obtained with the above series enable us to draw the following conclusions:—

1. That the various bronzes and brasses have a ratio of expansion less than that indicated by theory.

2. That, notwithstanding that the alloys Sn Cu₃ and Sn Cu₄ contain respectively 34.21 and 31.73 per cent. of a highly expansive metal—tin,—still their ratio of expansion is equal to that of pure copper, the presence of tin in these alloys having no influence on their rate of expansion.

(To be continued.)

On the Oxalates of Iron, by T. L. PHIPSON, Ph.D.,
Member of the Chemical Society of Paris, &c. &c.

THE two oxalates of iron of which I am about to speak have not yet been submitted to any investigation. They have been seen by several chemists, who have mentioned their existence in a cursory manner; but their composition and properties have never been examined.

In Nature there exists an oxalate of protoxide of iron, known by the name of *Humboldtite* (*Oxalite* or *Eisenresin* of some mineralogists), and which, according to the analysis of M. de Rivero, consists of one atom of oxalic acid and one atom of protoxide of iron. I have not yet had an opportunity of examining this mineral, nor have I endeavoured to form it artificially in the laboratory.

1. **Oxalate of Protoxide of Iron.**—When a dissolution of oxalic acid or of oxalate of ammonia is added to sulphate of protoxide of iron, and the mixture

violently stirred, a considerable quantity of a yellow precipitate is obtained in a short time. This bright-coloured precipitate is very stable, even in contact with strong acids. Neither air nor light have any action upon this new salt at the ordinary temperature of the atmosphere; it is, moreover, insoluble in water and in dilute sulphuric and hydrochloric acids; it cannot either be dissolved in any excess of oxalic acid. When treated with concentrated nitric acid, it is suddenly decomposed, with an abundant evolution of rutilant vapours.

The best method of analysing this salt I found to be the following:—By calcining the salt the iron can be estimated accurately as peroxide of iron; the other elements, water and oxalic acid, must be determined by combustion of the salt with oxide of copper, as in an ordinary organic analysis. The water is received and weighed in a chloride of calcium tube, and the oxalic acid calculated from the amount of carbonic acid produced by combustion:—

Two analyses made in this manner gave me the following results:—

	I.	II.	Theory.
Protoxide of iron . . .	19'44	19'40	20'00
Oxalic acid (by diff.) . . .	59'56 (by combust.)	59'75	59'99
Water (direct) . . .	21'00 (by diff.)	20'85	20'00
	100'00	100'00	99'99

This composition corresponds, therefore, with the formula,—

or, if we assume that oxalic acid contains hydrogen with the formula,—

When this yellow powder is submitted to the action of heat, it takes fire when its temperature is very slightly elevated, and burns like so much tinder, leaving a residue of very pure peroxide of iron. When ferricyanide of potassium is poured upon it, in sufficient quantity to obtain a partial decomposition only, a fine pale-green colour is formed, which might be used as an oil-colour or a water-colour, and the tint of which may be varied with the quantity of ferricyanide employed. When the decomposition with the latter salt is complete, the ordinary blue is obtained.

If the green powder, procured in the manner just stated, be thoroughly desiccated and then heated a little, it also takes fire and burns like tinder, leaving nothing but peroxide of iron.

3. Oxalate of Peroxide of Iron.—I obtained this salt by dissolving hydrate of peroxide of iron in an excess of oxalic acid; it is best to perform this operation at night or in the shade. A fine green solution is thus obtained, which, evaporated and then left to itself, soon gives emerald-green crystals. These are oblique prisms, and are very soluble in water.

When these crystals are exposed to the light of the sun they blacken on their borders, like chloride of silver; and if they be then sprinkled over with water, a peculiar crackling noise is heard, after which they dissolve, leaving a residue of yellow oxalate of protoxide. This experiment is very striking if a capsule, the bottom of which is covered with the crystals in question, be submitted to the direct influence of the solar rays,—one-half of the crystals being protected from the light by the projecting border of the capsule remaining unaltered; the other half of the crystals blackens rapidly.

The same decomposition takes place with the green solution. When this solution is exposed to solar light it gradually deposits yellow oxalate of protoxide of iron in microscopic crystals, and, in the space of a week or two, the whole solution becomes perfectly colourless. If a bar of iron be placed in the solution the reduction takes place without the influence of light, and a yellow powder of oxalate of protoxide is thrown down.

The analysis of these green crystals gave me the following result:—

	Found.	Calculated.
Peroxide of iron . . .	20'00	20'25
Oxalic acid . . .	45'00	45'58
Combined water . . .	24'00	22'76
Water of crystallisation . . .	11'00	11'41
	100'00	100'00

Whence we obtain the formula,—

or, if we suppose oxalic acid to contain hydrogen,—

The crystals lose their water of crystallisation at about 120° Centigrade, and, at the same time, their colour; when all this water of crystallisation is driven off they are perfectly white. The remainder of the water contained in the salt is only expelled by calcination. The same may be said of the greater portion of the water contained in the yellow oxalate of protoxide.

A curious fact connected with these two salts is, that the salt of protoxide is yellow, and the salt of peroxide green, contrary to what we generally remark with salts of iron. Generally, also, the salts of protoxide of iron are decomposed under the influence of exterior agents, and are converted into salts of peroxide, which are ordinarily more stable. In the cases before us precisely the reverse takes place.

The reduction of the peroxide salt into a salt of protoxide by the influence of light is very remarkable. It is, like all chemical actions of light, a phenomenon of reduction. I am not yet perfectly sure of what takes place in this circumstance. I have analysed the yellow salt deposited in this decomposition, and find it has for composition,—

In fact, that it is the same oxalate of protoxide of iron described above, and from which it differs only by being crystalline, the other being amorphous.

When we come to consider the constitution of these oxalates of iron, we may admit for oxalic acid the formula,—

which is probably the most rational manner of representing its composition; the oxalate of peroxide of iron, for instance, instead of—

becomes,—

and the oxalate of protoxide,—

The presence of *formic acid* among the products of distillation of oxalic acid authorises us to look upon oxalic acid as containing hydrogen. But, whilst admitting this, we cannot double the formula, as M. Wurtz has been obliged to do in supposing oxalic acid to be derived from glycol. In this theory oxalic acid is represented by $\text{C}_4\text{H}_2\text{O}_8 = 2\text{C}_2\text{HO}_4$; and it is evident that M. Wurtz's theory is completely erroneous, since if $\text{C}_4\text{H}_2\text{O}_8$ were the real formula of oxalic acid, it would be impossible to form salts such as those described in this paper.

On a New Principle in Volumetric Analysis.

In the *Annal. der Chemie und Pharmacie*, cxvi. p. 128, Dr. Mohr, of Coblenz, propounded a problem in volumetric analysis, and invited those interested in the subject to solve it. The first who did so was to receive one of Dr. Mohr's burettes as a prize. Dr. Mohr asserted at the same time that he had himself already solved it.

The problem was,—“To perform quantitative determinations without the use of weights, with volumetric solutions of unknown strength, and the strength of which must not be ascertained, and regulated.” Dr. Mohr received a number of communications, in which, however, some condition was violated; either a weight of some kind was used, or the strength of the test liquid was indirectly determined by saturated solutions of

chloride of sodium (as in Liebig's urea test), or in some other way.

The problem was first solved by Dr. Pauli, of the Union Alkali Works, St. Helen's, Lancashire, on December 28, 1860, in the following way. In one of the pans of a balance is put a piece of chemically-pure carbonate of soda, and in the other an equal weight of an undetermined soda, and both are measured by an acid of unknown strength. Suppose that in the first case 15 cubic centimètres, and in the second 11 cubic centimètres have been used, then, $15 : 11 :: 100 : 73.33$. The soda, therefore, contains 73.33 per cent. carbonate of soda.

The solution of the question, for which Dr. Pauli only cites a special case, is generally this:—

Equal portions of the pure substance to be determined and the impure are to be weighed off, one against the other, and are then to be measured with the same fluid; then the cubic centimètres used for the pure substance represent 100 per cent, and the other number proportionately less. Suppose, for example, that it is proposed to determine the iron in an iron ore. A piece of pure iron wire is placed in the scale of a balance, and is exactly counterpoised by means of the powdered ore, both are then brought into solution as protoxide in the usual way, and are then treated with permanganate of unknown strength. If oxide of iron is to be determined, pure oxide must be used instead of the wire. If potashes are to be examined, pure carbonate of potash (recently heated to redness) should be used. It would appear from this, for every analysis the strength must be determined by the pure substance. This, however, is easily avoided if we put a sixpence into the scale-pan, and weigh with this both the pure and impure substance. The number of cubic centimètres of the fluid holds good as long as the same fluid and the same sixpence are used, and this number may be marked upon the bottle as expressing 100 per cent. for the same substance.

This method is capable of universal application, and eliminates possible errors in weights and variations of temperature. It is only necessary that the substance to be determined should be available in the pure state. But how is the problem to be solved, if it remains as before, but with the further condition, "when the substance to be determined is not available in a pure state?" Dr. Mohr received two other solutions of the problem from Dr. Hiller and Herr Dietrich, both students in Heidelberg. Dr. Hiller has also solved the question, even with the condition that the pure substances should not be available, and in the same way as Dr. Mohr had already done it. For example,—if no chemically pure peroxide of manganese can be obtained for a manganese determination, according to Dr. Hiller, pure permanganate, or pure bichromate of potash, can be employed to weigh off the manganese; both are then converted by distillation with hydrochloric acid into chlorine, and then into iodine, and both fluids are then to be determined with the same unknown solution of hyposulphite of soda. Instead of using pure permanganate, it would be better perhaps to use pure iodine to counterpoise the manganese, then to dissolve the iodine in iodide of potassium, and proceed as before. We have now to convert the value of the iodine into the value of an equal weight of pure peroxide of manganese, and express it in the cubic centimètres of hyposulphite used. As 43.57 MnO₂ set 127 iodine at liberty, therefore any given weight of MnO₂ would set at liberty $\frac{127}{43.57}$, or 2.915 times as much iodine as is employed to counterbalance it. We have, therefore, to multiply the number of cubic

centimètres of hyposulphite which have been used for a quantity of iodine equal to the manganese by 2.915, and then to proceed as if pure MnO₂ and common manganese had been weighed together.

If pure carbonate of soda cannot be obtained, pure carbonate of lime may be used; the cubic centimètres of the acid used must be multiplied by $\frac{40}{33}$, that is, 1 atom of carbonate of lime divided by an atom of carbonate of soda.—*Annalen der Chemie und Pharmacie*, cxvii. 386.

TECHNICAL CHEMISTRY.

On the Chemical Composition of Cast Iron and Steel,
by M. FREMY.

(Continued from page 346.)

To establish clearly the existence of a nitrogenised charcoal, I have had recourse to a synthetic experiment which clears up all doubt on the subject. I made choice of a very pure organic matter,—for instance the best quality of sugar, nitrogenising it according to the invaluable directions given in a recent communication by M. Paul Thenard, and then submitting the compound to prolonged calcination—the charcoal thus obtained is highly nitrogenised, and disengaged ammonia for a long time by the action of hydrogen.

These experiments prove that organic nitrogenised substances, such as those composing animal and even vegetable tissues, will by calcination yield a nitrogenised charcoal, which by slow combustion, like that produced in cementation cases, will then disengage its nitrogen in the state of ammonia under the influence of hydrogen or of aqueous vapour. Nitrogenised charcoal is then a sort of magazine of nitrogen suitable for cementation; it decomposes with a degree of slowness favourable to the operation itself, and is perhaps one of the conditions of the quality of the product.

The facts I have brought before the Academy will probably be utilised in manufacture, and will account for certain practical operations well known among steel-workers. Thus all the organic bodies which produce rapid acieration, such as horn, soot, leather, animal excreta, are precisely those which yield highly nitrogenised charcoal. Ammoniacal compounds can nitrogenise even ternary organic substances.

The utility of nitrogen in charcoal explains a very curious practical fact, which is, that the charcoal of the cementation cases, after having been heated for a certain time, becomes exhausted, and requires to be replaced by fresh charcoal. The old theory, which assigned to carbon an exclusive part in cementation, could not account for this fact, admitting that the nitrogen is in the end carried off by the action of hydrogenised bodies, which, according to my novel views, is perfectly intelligible. The nitrogen for converting iron into steel is then yielded both by air and by wood charcoal, which always contains nitrogen. A notable quantity of nitrogen may even pre-exist in iron; the purest sorts of iron, and which are most easily convertible into steel, are just those containing nitrogen.

By submitting certain kinds of iron to the action of essence of turpentine vapours, I have sometimes produced an evident degree of acieration. As an explanation of this phenomenon, I have always found on examining the metal afterwards, that it contained nitrogen. Thus, those chemists who deny the influence of nitrogen in producing steel with carburets of hydrogen or diamond, are greatly at fault, for ordinary iron often

retains sufficient nitrogen to form steel by the action of a simply carbonising body. Moreover, I shall by-and-by prove that nitrogen can be replaced in acieration by another metalloïd bearing some chemical analogy to it, such as phosphorus, and yield compounds which may easily be confounded with normal steel.

After showing that steel is always produced in presence of nitrogen, the influence of this body being proved by laboratory experiments and practical observations, I must now inquire in what way nitrogen influences acieration.

As I said in a preceding communication, the action of nitrogen in acieration is twofold; not only does it combine with the iron, but it renders the metal porous, and makes clear the hitherto obscure phenomenon of cementation, namely, how a solid body can penetrate a metallic mass.

The most distinguished savants engaged in enquiries touching acieration know that cementation is a fact difficult to comprehend. I am about to prove that the properties of nitride of iron permit the most simple explanation of this penetration of the metal. In fact, it has been shown that nitrogen furnished by ammonia can penetrate a mass of iron and produce the compound I have studied under the name of nitrogenised iron; this body submitted to the action of hydrogen is reduced, leaving the metal remarkably porous. Steel is produced by heating this nitrogenised iron in a current of carburetted hydrogen gas; a portion of nitrogen remains combined with the metal; carbon can then penetrate the pores produced by the departure of nitrogen and the disengagement of hydrogen or of ammonia.

All the mysteries of cementation are thus easily explained; the numerous blisters characterising cementation steel—blistered steel, as it is called—the formation of which it was impossible to explain by the old theory, are now intelligible: they are produced by gases resulting from the action of hydro-carburised compounds on nitride of iron. Thus, the chemical phenomena of cementation may be summarised in the following manner:—Ammonia produces nitrogenised iron in disengaging hydrogen, which renders the iron porous; the hydro-carburetted gases then decompose the nitrogenised iron, acting by their hydrogen and carbon; excess of nitrogen is disengaged in the state of ammonia or cyanide of ammonium, which increases the porosity of the metal; while the carbon unites itself to the remaining nitrogen, forming the nitro-carburetted compound which seems to be the element essential to the composition of steel. This twofold action of nitrogen, which M. Despretz's experiments foreshadowed, is in a theoretical point of view an exceedingly interesting fact.

Is it not curious to see nitrogen, whose chemical activity is usually so little developed, combining with two bodies present in cementation cases, playing the part of a shuttle, and becoming a powerful cementation agent? It is impossible to consider the important part which I make nitrogenised iron play in cementation as a theoretical idea unconfirmed by experience. It cannot be forgotten that nitrogenised iron is produced at red heat, and that I have maintained it at that temperature for ten hours without its decomposing, and that, when afterwards submitted to a carburising influence, it has formed steel. These are precisely the conditions which we find realised in cementation cases.

I have now to inquire whether, in the fabrication of steel, by refining cast iron, nitrogen exerts an influence as important as in cementation. I first prove that in steel produced by puddling, or by a small furnace, the

presence of nitrogen is easily shown, either by making a current of hydrogen act on the filings, and so disengaging ammonia, or by examining the nitrogenised residue resulting from the action of acids on this kind of steel.¹

Steel produced in a small furnace, in contact with wood charcoal, and, consequently, under circumstances in which cyanides are readily formed, the nitration of iron and its transformation into steel can easily be understood.

In puddling furnaces acieration is sometimes due to the nitrogen contained in cast iron, but chiefly to the action of nitrogenised compounds furnished by the combustible, and the air, which acts rapidly on the iron when it commences to become red, porous, and in a nascent state.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Friday, March 8, 1861.

Discourse on some Phenomena attending Combustion in Rarefied Air, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

THE results which I shall endeavour to lay before you this evening originated in a series of observations which I undertook when accompanying Dr. Tyndall in the ascent of Mont Blanc in the autumn of 1859. I then took with me a number of candles—half-a-dozen stearine candles, in fact—which were carefully weighed in Chamounix before the ascent, and were burned there for the space of an hour. These candles were subsequently taken to the top of the mountain, and were there carefully burned again, with the complete exclusion of draft for the space of another hour. On returning from the summit the candles were again carefully weighed, and the difference between the two results would indicate, of course, whether an increase of atmospheric pressure had had the effect of causing the combustion to go on more rapidly; or, on the other hand, whether rarefied air had the effect of decreasing the rapidity of combustion. We might naturally suppose that, inasmuch as at the summit of Mont Blanc we had not much more than half the amount of air, in the same bulk that we had at the level of the sea, that we should meet with a diminution in the rate of combustion of such materials as candles. The results of those experiments which, as I have said, led me to the investigation forming the particular subject of my discourse this evening, are contained in this table, which shows the difference in the rate of combustion of the same candles at Chamounix and at the summit of Mont Blanc.

Rate of Combustion per Hour.

At Chamounix.			At the Summit of Mont Blanc.		
1st candle	lost	9.2 grammes	1st candle	lost	8.7 grammes
2nd	"	" 9.9 "	2nd	"	" 9.5 "
3rd	"	" 9.2 "	3rd	"	" 9.2 "
4th	"	" 10.4 "	4th	"	" 8.8 "
5th	"	" 9.5 "	5th	"	" 9.3 "
6th	"	" 9.2 "	6th	"	" 9.0 "

If we add up these results together and take the mean we shall find that the rate of combustion at Chamounix was

¹ Chemists wishing to prove the presence of nitrogen in steel by means of hydrogen must avoid the numerous influences which decompose ammonia. They must, besides, seek for nitrogen when not rendered evident by hydrogen, either in the liquids proceeding from the action of acids on steel, or in the brown, insoluble substance resulting from this action. Very pure hydrate of potash can also, when hot, disengage the nitrogen contained in steel.

9.6 grammes per hour; and at the summit of the mountain the rate of combustion was 9.1 grammes per hour. But you see that one of these candles No. 4 yielded abnormal results. There was evidently something the matter with this candle which caused it to burn an abnormal quantity of stearine at Chamounix, and the quantity burned was a trifle smaller at the summit of the mountain than that burned by the others. It would, therefore, I think, only be fair to leave this fourth candle out of the question, and then we arrive at this average result, omitting the fourth candle, that the quantity of stearine burned was 9.4 grammes at Chamounix, and at the summit of the mountain 9.2 grammes per hour. So you see we can assure ourselves by this result, that the rate of combustion is entirely unaffected by the pressure of the atmosphere, and that candles and combustibles of that kind burn with exactly the same consumption of combustible matter under one circumstance as under the other. Whilst making these experiments in the tent at the top of the mountain, where we remained twenty-two hours, I was very forcibly struck with the difference in the character of the flame. The flame of an ordinary stearine candle with which we are all very familiar, exhibits generally this phenomenon—we have at the lower part of the flame a blue portion which does not, however, rise to within a quarter of an inch of the apex of the wick, there it terminates, and at this point the luminous portion of the flame commences. When the same candles were burned at the summit of the mountain, I noticed that this blue portion of the flame now extended to about an eighth of an inch above the apex of the wick, consequently the candles gave a very much smaller amount of light. The luminous effect was obviously, to the most casual observer, considerably inferior to the luminosity of the same candles at the base of the mountain. This led me on returning to England to institute a series of experiments upon this subject, and I found that on burning a candle in air rarefied to the extent to which it was rarefied on the summit of Mont Blanc the illuminating power of the candle diminished rapidly, and to a very considerable extent. The experiment was made in the apparatus here upon the table, and I cannot do better than repeat it in the way in which it was made. Here we have our stearine candle enclosed in a glass cylinder in connection with a powerful air-pump, by means of which we can obtain any amount of rarefaction within the cylinder. External air can be admitted below, and the products of combustion be carried off by a glass chimney, or cylinder, which is about an inch and a-quarter in diameter, and is connected with this tube, so that the products of combustion are thus carefully removed, and the candle is kept constantly burning in pure air, a condition which is obviously quite essential to the proper performance of the experiment. Now we will endeavour to light our candle. [The exhaustion of the cylinder was then commenced.] We have already a rarefaction of air to the extent of some twenty-four or twenty-five inches I believe. We have lighted our candle. We have here a stop-cock, which will enable us at pleasure to regulate the supply of external air. The candle is now burning at the ordinary atmospheric pressure, and giving its ordinary amount of light. You know when we first ignite a candle, it burns with a dull flame, or a small flame at all events, until a certain quantity of stearine has got melted. Whilst the flame is improving I will project upon the screen the image of a vacuum gauge by which you will be able to see the tension of the air which we have in our exhausting apparatus during the different stages of combustion. [The lights were then turned down.] There [pointing to the image on the screen] we have our vacuum gauge, which I hope will be visible even to those at a distance. This is a column of mercury which is gradually rising. We will take our barometer to be at 30 inches, the usual atmospheric pressure. The gauge is

now, you see, at 22.5, the next figure being 22, therefore we have a pressure of about 8 inches; and at this pressure we will introduce our burning candle. You see now how I am reducing the pressure, and notice the effect upon the luminosity of the candle. Now our candle, you see, is burning under a pressure of about 8 inches of mercury, instead of about 30 inches, and if we had the means here of taking the illuminating power there can be no doubt that we should find we have now a very small fraction of the light given by this candle before the exhausting process took place. Now we will gradually allow this pressure to increase. In fact, we shall find it necessary to let a little air in. You see it is gradually rising—the mercury is gradually falling. We had first 22.5, now 22, and now it is going down to 21. Now, our candle is burning in a pressure of 10 inches, and you see the pressure is gradually increasing. You will notice that we have a corresponding increase in our illuminating effect. Our candle, which was barely luminous at all under a pressure of 8 inches of mercury, is now considerably more luminous when that pressure is increased to something like 18 inches, at which it now stands. Now we have a pressure of 18 inches—in fact, a little more. There we have now about the light that the candle gave at the summit of Mont Blanc, and which is obviously very different from the light of a candle, burning with its usual brilliancy. We will just restore the candle to its original atmospheric pressure, and without disturbing the equilibrium of its combustion. Now that our candle is burning under atmospheric pressure, you see what a very different result we have with regard to the light that is emitted.

I did not call your attention to a phenomenon which is perceptible at a short distance from the candle when the illuminating effect is diminished to its lowest point—a phenomenon which is very beautiful if it can be seen; but, unfortunately, it cannot be seen at a distance. It is this: when the luminous portion of the flame of the candle has almost entirely disappeared there suddenly appears, round the nucleus of the flame, another flame which had hitherto been invisible if it had existed at all; it extends to the width of about a quarter to half an inch on each side of the flame, and it is of a very beautiful purple tint. It can only be well seen when the light from the centre part of the flame is cut off by holding the finger or a piece of card before the flame sufficient to intercept the rays from the centre part. When that is done this beautiful colour in the external coating of flame comes out very beautifully. This coloured flame I have examined by means of the prism, and it appears to possess those rays which are permitted to pass by a solution of permanganate of potash, although it contains rather more blue rays, apparently, than the light transmitted by the permanganate; I will endeavour to show you the kind of rays which are perceptible in the flame of the candle by means of the prismatic spectrum. [The gas-lights were again turned down.] Now, we will endeavour to throw upon this screen, first of all, the prismatic spectrum itself containing all the usual colours and then we will cut off the necessary colours. There, we have this beautiful spectrum which, you see, contains at this extremity an intense red ray, then orange, then yellow, then green, then blue, then indigo, and finally violet. Now, the external flame of the candle which is seen so beautifully when you are near to the candle, and when, through the rarefaction of the air the luminosity of the flame has become almost extinct, contains a combination of the rays from the two extremities of the spectrum; it contains a portion of this red ray and it contains a portion of this violet ray. I will now introduce a solution of permanganate of potash which, as I have said, resembles the colour of this outer flame. [A beam of electric light was passed through a solution of permanganate of potash, the two colours of which were thereby shown upon the

screen.] These are the colours of which the external coating of the flame is composed. If we have a mixture of these two colours, red and violet, you will get something like a notion of the colour of this external flame of the candle which is seen when the luminosity has almost disappeared. Here we have something nearly approaching it. Now, this effect is very curiously connected with a result that was first observed by Mr. Gassiot in the transmission of electric sparks through highly rarified air or highly rarified gases. Mr. Gassiot found that when these gases contained even a trace of nitrogen that the colour at once became of this pinkish hue—became quite similar to what we have observed in the external flame of the candle. I cannot do better, perhaps, than just show you this colour, which is, perhaps, more than any other colour like that of the external flame; in fact, I believe the cause of the colour in both cases to be identical—namely, the ignition of nitrogen; and that this spectrum which I have been showing you on the screen, is really the spectrum of incandescent nitrogen. Here we have nitrogen in this tube which has been highly rarefied; it does not contain more, perhaps, than from one-tenth to two-tenths of an inch of mercurial pressure. [The rarefied nitrogen was contained in a long cylindrical glass jar, through which a series of electric sparks were then transmitted.] There is the light in question which is, I believe, due to exactly the same cause as that light surrounding the candle flame—namely, the incandescence of the nitrogen in both cases.

Upon commencing these experiments so as to bring them into strictly quantitative form, and ascertain with something like precision what is the actual diminution of light which takes place under these circumstances, I soon found that candles were perfectly useless for this purpose, and that when placed under these artificial conditions, candles, notwithstanding the quality of the materials of which they may be made, are liable to gutter; they burn with different lengths of wick, and the results, which occupied me several weeks in obtaining, were altogether unreliable. I therefore turned to gas, as being far more manageable and capable of uniform combustion under these, so to speak, abnormal conditions. We can, by means of a gas meter like this, regulate the supply of gas into this apparatus, and thus we have at our command a known quantity of combustible matter to be consumed in a certain time. The light emitted was measured by Bunsen's photometer, an instrument which is very well known. It consists of a central disc of paper, which is rendered transparent in the greater part of it by means of a solution of spermaceti in turpentine; and if this disc be placed between two sources of light in an otherwise dark room, and you move it until the illumination of both sides is equal, that equality of illumination will be manifested by the disappearance of that comparatively non-transparent spot of unsized paper in the centre of the disc; and by these means it is quite possible to determine, and with very considerable precision, the illuminating power of any flame. Here, to describe the apparatus employed, is a gas flame the combustion of which was rendered quite constant by passing the gas through a governor, regulating the pressure of the gas. Then the experimental gas flame was placed at the opposite extremity of the instrument, and this was graduated by a scale, so that on moving this disc, both sides of it could be simultaneously seen. This is, in fact, Bunsen's photometer. The first series of experiments was commenced with a pressure of 29.9 inches of air, and in each case I assumed the light of the experimental flame to be equal to 100, for the purpose of comparing the results. On reducing the pressure to 24.9 inches, the amount of light was decreased to 75. On reducing the pressure to 19.9 inches, the illuminating power was reduced to 52.9. Then, on reduction to 13.6 inches of pressure, the illuminating power was reduced to 20.2. On reducing it to 9.6,

the illuminating power was reduced to 5.4, and finally, when the pressure was reduced down to 6.6, the illuminating power fell to 0.9, the fraction of a unit; so that you see we have decreased from 100 units of light down even to less than one unit. The light emitted by the combustion of the same kind of gas under this reduced pressure was not $\frac{1}{10}$ th of the light under the ordinary atmospheric pressure.

This is the second series of experiments which were made.

Second Series.

Pressure of Air.	Illuminating Power.	
	Observed.	Calculated.
30.2	100	100
28.2	91.4	89.8
26.2	80.6	79.6
24.2	73.0	69.4
22.2	61.4	59.2
20.2	47.8	49.0
18.2	37.4	38.8
16.2	29.4	28.6
14.2	19.8	18.4
12.2	12.5	8.2
10.2	3.6	— 2.0

Each number is the result of the average of twenty observations—not merely a single observation, but the average of twenty in each case. This table goes down to 10.2 inches of pressure. Now, the result of these observations was this—that beginning at atmospheric pressure, and with 100 units of light, we decrease almost exactly at 5.1 units of light for each inch of mercurial pressure we diminish in coming down the scale. The results of these two series of experiments are seen upon this diagram, which will give you a clearer idea of the nature of these results and the accordance with each other, than any mere inspection of the tables.

In this table the amount of light is represented by the horizontal lines. Here, beginning with no light at all, at the bottom of the table, you have 10, 20, 30, 40, 50. The perpendicular lines represent the amount of pressure—30 inches, 28, 26, 24, 22, 20, and so on. The black diagonal lines show the results of the two series of experiments. You see, therefore, that if the illuminating power of the flame had been constant for all pressures, then this line, instead of running down here diagonally, would run straight across the diagram. If, on the other hand, the illuminating power decreased

exactly in the same ratio as the pressure—for the distance from 100 to nothing is exactly the same as from 30 to nothing on the horizontal line here—then this line would proceed from this angle direct to the opposite angle [pointing]; but you see the light diminishes in a more rapid ratio than the pressure. You find, also, another peculiarity—that, when you get down to something like 15 inches of pressure, there is a sudden divergence in that direction [pointing to the right of the diagram], showing that the light does not then decrease in so rapid a ratio as at a higher pressure; in fact, that, from 14 or 15 inches downwards, the decrease in the illuminating power is considerably less rapid than from 30 inches down to about 14 or 15. Taking, however, the atmospheric pressure down from 14 inches, we have then a series of descending steps, so to speak, representing, for each unit in the diminution of pressure, a diminution of nearly 5·1 units of light. We have upon these tables the calculated results upon this assumption, and you see how nearly they coincide with the observed diminutions in the experiments. Now, as the diminution of light for a comparatively small diminution of pressure is so great when we are operating nearly at atmospheric pressure, it became interesting to ascertain, by as delicate a series of experiments as could be made, the variations within three inches of mercurial pressure, and they were made in the same way as the above, but with a water-pressure gauge, so that the readings were considerably more delicate. The following figures are the result of twenty observations under each pressure:—

Third Series.

Pressure of Air.	Illuminating Power.	
	Observed.	Calculated.
30·2	100	100
29·2	95·0	94·9
28·2	89·7	89·8
27·2	84·4	84·7

Here, in the second column, you have the observed numbers, and in the third the calculated numbers, at the rate of a diminution of 5·1 units of light for each inch diminution of pressure. You see the line is almost perfectly straight, and coincides so nearly with the divergence which is represented here by this dotted line that somewhere about half way up the diagram the two lines coalesce and remain together during the rest of their passage to the top corner of the diagram. In both diagrams the dotted line represents the calculated numbers.

These, then, being the results of the combustion of gas and candle flames in rarefied air, some questions naturally arise as to what can be the cause of these phenomena. Before answering these questions, it would be well for us, perhaps, for a moment or two to glance at the conditions under which light is evolved from flames in general. In gas and candle flames the light is due to two sources; namely, first, the incandescence of gaseous matter, and secondly, the incandescence or glow of solid matter deposited within the flame. Now the light due to the incandescence of gaseous matter is so slight—does not certainly amount to more than 1 per cent. of an ordinary gas or candle flame—that it may be left out of consideration altogether, and it only comes into prominent play when we get to a very high degree of rarefaction, but it is a light which suffers little diminution, and hence it causes the experimental lines in the diagrams to diverge at low pressures from the calculated line. The incandescent gaseous matter retains the total luminiferous effect higher than it otherwise would be if this light from gaseous incandescence were subject to diminution by the rarefaction of the air. Here is one of the incandescent gas flames—namely, hydrogen. We have two of them in coal gas—namely, hydrogen and carbonic oxide. You see the light from that large amount of flame is scarcely worthy of consideration at all; but if we introduce into the flame some solid matter which is capable of being heated to incandescence, we shall at once obtain a much more powerful light—we shall, in fact, feed this burner with exactly the same hydrogen gas from the same source as that from which the other burner is fed, and the only difference in the two experiments will be, that into this hydrogen flame we have introduced a quantity of platinum wire coated with a little film of lime, which is obtained by burning upon the wire paper that has been immersed in chloride of calcium. [The lights were then turned down.] Here we have now the same flame with this solid matter immersed in it, and you see the difference in the amount of light emitted at the same temperature, for the flame has not increased in temperature—it has perhaps rather diminished in temperature by the presence of this platinum gauze. [The lights were then turned up.] Thus the presence of solid matter is one condition for the production of a considerable amount of light in flame. But it may be objected that if we require solid particles of matter in a flame—if we assume that in ordinary flames we have solid matters present—those solid matters ought to be capable of being perceived, and that flame, in fact, ought to be to a certain extent, opaque, owing to the presence of those solid matters floating within it. Such is, however, not the case. Flame is almost perfectly transparent; if devoid of smoke, it is practically quite transparent. I will endeavour to show you this by ascertaining whether we cannot, through a considerable body of flame, actually read a newspaper. I will just illuminate a printed paper by means of the electric lamp, and project an image of it upon the screen. There we have, I think, a tolerably readable page. I think no one would have very great difficulty in reading that. Now, I will interpose this gas-flame between the paper and the screen. You see there is an image of the flame upon the screen, but it does not in the slightest degree interfere with the reading of the paper. The transparency is so nearly perfect as not to affect the legibility of these printed letters. So that this mass of flame which appears to have substance in it, is to all intents and purposes, transparent. You may make the experiment yourselves if you hold a piece of printed paper very near a gas-flame, and look very closely at it; you can read through the thickest portion of the flame without difficulty. But we may prove in another way, and by means of the electric lamp, that solid particles may be and really are carried across a perfectly transparent space, and if I project the image of these carbon points from which we

obtain our light, on the screen we shall see between them a perfectly transparent portion, apparently quite free from solid matter, but through which particles of solid matter in great quantities are constantly passing. Dr. Tyndall will be kind enough to throw these points upon the screen, and then we shall have the luminous image of the prisms of carbon which are brought nearly into contact, and between which the electric current is passing, bridging over the space; there we have them shown on the screen. I want you to notice the lower of these points; you see how it is growing—how there is a sort of branching out of that point towards the upper one, which is caused by the transference of the particles of carbon from one point to the other. The space between the points is perfectly transparent just as our gas-flame was, although these particles of carbon in the solid form are being carried over. See how they are growing upwards from the lower point, and how the upper one is wasting. That growth will take place through a considerable space of air, which, however, remains transparent all the time. The light of flame is also greatly dependent upon the temperature of the flame. With the same amount of solid matter floating in the flame the light augments by an increase of temperature, and *vice versa*. [The lights were then turned up.]

These being, then, the general conditions upon which the light of flames depends, the first question that will naturally arise to our minds will be this,—Is the combustion which takes place in rarefied air a perfect combustion; because if it be an imperfect combustion, for a given amount of combustible substance consumed, the quantity of light would be considerably less than that which would be otherwise obtained? I have therefore investigated the point with considerable care, and having extracted the gases that were passing off from the flame, both when the candle was burning under ordinary atmospheric pressure, and when under a pressure of eight inches of mercury, I found that in both cases the combustion was perfect. There was not a trace of carbon escaped unconsumed; therefore the combustion, both in atmospheric and rarefied air, was perfect. In fact, if I may be allowed the expression, the combustion in rarefied air was more perfect; for there was a more rapid conversion of the elements of combustible matter into their final oxidized products—carbonic acid and water. This question, therefore, as to whether the diminution of light is caused by an imperfect combustion, must be answered in the negative. The next question that will arise is this,—Is the diminution of light caused by a diminution of temperature? It is well known that if you allow air to escape out of a vessel into another vessel containing rarefied air, or into another vacuum vessel, there is a considerable diminution of pressure in the one from which the air escapes, and it might not be unfairly concluded that the temperature does suffer in this way. But I believe this diminution of temperature, from the cause just mentioned, is practically very small, and is neutralized to a great extent by the smaller cooling effect of the atmosphere; the atmosphere being more rare, the quantity of heat taken away from the flame, and the amount of heat carried away by convection, is smaller than in ordinary circumstances. That this is so, may be rendered evident by a very simple experiment. We will ignite a platinum wire in such a way under the receiver that the incandescence shall be scarcely apparent. [The platinum wire was then rendered slightly incandescent by a current of electricity from six of the battery-cells.] You will notice now the extent to which that wire glows while we extract the air, and I think it will be noticed that as the rarefaction goes on, the intensity of that glow will increase. If you notice the illuminating effect within the jar, you will find it very considerably increased by this rarefaction of the air. Here we have in this electric current a constant source of heat, but the cooling effect of the air is diminished by the rarefaction,

and consequently the wire becomes hotter, owing to the less amount of heat being extracted from it. This is the case with the flame of the candle, and this effect makes up nearly for the somewhat lower temperature that is produced by the combustion of the flame, so that this question must also be answered in the negative.

Now we come to a third question, namely, Is the diminution of light due to admission of atmospheric oxygen into the interior of the flame? If atmospheric oxygen could gain access to the interior of the flame then it would undoubtedly have the effect of destroying these incandescent particles of carbon which are now in the interior of the flame, and consequently of withdrawing the very source upon which $\frac{2}{3}$ ths of the light depends. It is well known that air introduced into a gas flame has the effect of gradually diminishing the light. We have here an ordinary gas-flame giving the usual amount of light, and an arrangement by which we can show the effect of atmospheric oxygen upon the flame. Our supply of gas is regulated by this stop-cock. The gas passes along this tube and into the burner. Here we have a second tube inserted into the gas-tube, through which we can throw atmospheric air contained in this air-holder. Notice the remarkable effect upon the flame. We have got now the maximum illuminating power. Now I have admitted the smallest possible quantity of air. It has not yet reached the flame, but it will presently. You see at once, when the air comes into the flame, how gradually the size of the flame is reduced. If we had the means of measuring the illuminating power, we should find that power reduced also. We will now admit a further quantity of air, and you see, as soon as it reaches the flame, how the light is reduced. There is no doubt that this is the principal, if not the only cause of the diminution of light in these gas and candle flames. But how does the oxygen gain access to the interior of the flame in greater quantity in rarefied air than it does in condensed air? The cause is very easily explained. If you have a very rare or light gas, the particles of that gas are capable of moving about in all directions with very much greater facility than the particles of a comparatively dense gas. Hydrogen is very remarkable for what is termed its "mobility"—its power of intermingling itself with other gases. A jar of hydrogen left for a few moments with its mouth open downwards, exposed to the air, will lose all the hydrogen contained in it. The gas will rapidly pass out to the external air, even though the mouth of the jar be downwards, and consequently the gas has to go out against its own comparative lightness, and to make its way against gravity downwards. So when you rarefy the air contained in this vessel, the particles of the air are far more mobile than when the air is at the ordinary pressure, and they gain access into the interior of the flame with far greater facility. It has been found that when a candle or gas flame burns in air at the ordinary pressure, that as much as from 60 to 70 per cent. of nitrogen gains admission into the interior of the flame. Now, if we withdraw the gases from the interior of the flame as far as the flame remains blue, you find oxygen present. It is only when you get higher into the luminiferous portion of the flame that there is nitrogen and no oxygen. The presence of oxygen in the flame determines at once the combustion of the carbon particles, which constitute the source from which the light emanates under ordinary circumstances.

I feel it necessary to apologise for having brought these simple experiments before you. I have done so in reliance upon that interest which I know those who weekly assemble here feel in any new scientific fact, however abstract and technically valueless it may appear to be. I do not know that any useful application can be made of this law regarding the reduction of illuminating power; but possibly, if we find that this effect extends upwards to higher pressures, some such application might be made.

I have only yet been able to make a few experiments in this direction, but so far as they go, they seem to indicate that the same law holds good for higher pressures, and that at two atmospheres we should have about $2\frac{1}{2}$ times the illuminating power which we have at the ordinary atmospheric pressure, thus greatly increasing the amount of light obtainable from a given quantity of combustible matter. These phenomena of flame did not escape Davy in his laborious and beautiful researches upon flame, although he does not appear to have paid more than a passing attention to the effects of pressure upon the light of combustion.

Weekly Evening Meeting, Friday, March 15, 1861.

A Lecture on Electrical Quantity and Intensity,
by LATIMER CLARK, Esq.

(Continued from page 355.)

The instances in which the quantity present is not simply dependent on the tension, are those in which other electrified bodies are present which, by their inductive influence, affect the quantity present in all bodies in their vicinity without necessarily affecting their tension. An insulated cylinder was connected with the positive pole of a Daniell's battery of 600 cells, its negative pole being connected with the earth; so that the cylinder was in a condition to give off a powerful and visible current to another wire connected with the ground; in this condition a positively electrified disc was approached to it and by its inductive influence was shown to render one end of the cylinder electrically negative so that a carrier ball applied to that end showed it to have a negative charge, thus presenting the apparent paradox of a negative electrified body giving off a positive current to the earth, or *vice versa*. One end was negatively electrified, and the other end positively, but the tension was the same everywhere.

According to the ordinary way of regarding this class of phenomena, it was usual to state that the ends of the cylinder acquired a state of positive or negative intensity, or that they had their intensity changed: it was contended that this gave an inaccurate idea of the real nature of the change, and that the approach of an electrified body, however near or however violently it might be excited, could not in the slightest degree affect the tension of a conducting body, which was in connection with the earth; the only influence it could have would be to alter the quantity in the second body, by driving a portion of its electricity downwards to the earth. It might be assumed as a law that the tension of the electricity in every part of a conducting body of moderate dimensions was the same, notwithstanding the vicinity of other electrified bodies. If a positively electrified body were brought near an insulated conductor, the distribution of the electricity in the second body was changed, and its whole tension was raised, but the tension remained everywhere uniform, and was as high at the negative as at the positive end.

The fall of tension in electricity was always accompanied by its conversion into heat; the ignition of wire by the voltaic current, the intense heat of the voltaic arc, and the heat and light of the electric discharge and of the spark, were all cases of the evolution of heat consequent on the fall of tension, and the quantity of heat evolved was apparently directly proportionate to the fall of tension within a given space and to the quantity of electricity passing.

In the case of electric telegraph conductors and submarine cables, it was shown, from a carefully-conducted and extensive series of experiments, that the tension falls with the most perfect regularity from the positive pole of the battery to the end in connection with the earth, in accordance with the law of Ohm; and since the quantity of electricity held under induction varies in the same ratio as the tension

the distribution of the charge in a cable follows precisely the same law. It results from this, that if a cable with a current flowing through it, be divided into any number of equal sections, and the quantity in the section connected with the earth be taken as unity, the quantities in all the other parts, whatever their number, will be in the ratio 1, 3, 5, 7, 9, 11, &c. So that if a cable be divided into two halves, the quantities will be in the ratio of one to three.

The Speaker stated that he had ascertained that, in the voltaic battery, the presence of two metals was not an essential condition—the negative metal was not necessary for the formation of the electric current, but only for its after detection and exhibition. A simple mass of copper, iron, zinc, or any oxidisable metal, when laid on the moist earth, formed a complete battery in itself, giving positive electricity to the earth, and quickly assuming a negative tension, which it would communicate to any other body resting on it or in contact with it, as for instance, a length of submarine cable. If a cable thus charged were afterwards removed and applied to any more electro-negative metal, such as platinum, or to carbon, the charge would return to the earth; and it was found by measurement that the charge thus acquired by a cable was exactly the same as if the two metals had been employed simultaneously in the ordinary form of a galvanic couple. If the mass of zinc were permanently connected with the non-oxidisable or less oxidisable metal, and thus with the earth the tension, being constantly destroyed and as constantly renewed, would form a constant current, becoming in fact a voltaic couple. If the connection with the earth, instead of being made through another metal, were made through any inert conducting substance or liquid, the same constant current would be produced, thus forming the well-known case of a voltaic battery with one metal and two liquids.

After the conclusion of the discourse, Mr. Clark stated, with reference to Faraday's discovery of specific inductive capacity, that in the course of some investigations conducted in conjunction with Professor Hughes, they had observed that every different dielectric possessed its own specific law of variation of inductive capacity with respect to distance. With air it varied as the distance, inversely; but with gutta-percha it was more nearly as the square root; with India-rubber and white wax it was intermediate between the two ratios, and the law of variation was different with every substance tried. From which it would result that observers who deduced the specific inductive capacity of any material from experiments on half-inch plates, would arrive at very different results from others who operated on inch plates.

CHEMICAL SOCIETY.

Thursday, May 2, 1861.

R. WARRINGTON, Esq., in the Chair.

T. Griffiths, Esq., was elected a Fellow.

Mr. JOHN DAVIDSON read a paper "On the Action of Dibromide of Ethylene on Pyridine." A mixture of the two substances with about one-sixth of its volume of alcohol was heated in sealed tubes to 100°C ., whereby a silky crystalline mass was obtained. Representing pyridine by the formula $(\text{C}_5\text{H}_5)'''\text{N}$, this new product would be the dibromide of ethylen-dipyridyl-diammonium, $(\text{C}_5\text{H}_5)''(\text{C}_5\text{H}_5)_2'''\text{N}_2\text{Br}_2$, corresponding to one of the principal products of the action of dibromide of ethylene on triethylamine, namely, the dibromide of ethylene, hexethyl, diammonium $(\text{C}_2\text{H}_4)''(\text{C}_2\text{H}_5)_6\text{N}_2\text{Br}_2$. By acting on the new dibromide with chloride of silver, the corresponding chloride was obtained, which formed with dichloride of platinum, the double salt $(\text{C}_5\text{H}_5)''(\text{C}_5\text{H}_5)_2'''\text{N}_2\text{Cl}_2 \cdot 2\text{PtCl}_2$. By treating the dibromide with freshly precipitated oxide

of silver, the corresponding dihydrate was obtained as a colourless powerfully alkaline but unstable liquid.

Professor BLOXAM read a paper "*On the Amounts of Water Expelled from the Hydrates of Potash, Soda, and Baryta, by Boracic and Silicic Acids.*" The Author referred to his former experiments, which showed that one atom of boracic acid BO_3 at a bright red heat expelled one atom of carbonic acid CO_2 from carbonate of potash, two atoms from carbonate of soda, two and a-half atoms from the carbonates of lithia and baryta, and three atoms from carbonate of strontia. Hence, he inferred that boracic acid was tribasic, but that in some cases it was unable to satisfy its saturating capacity, on account of the affinity of some of the bases for CO_2 . The affinity of these bases for HO , being less than those for CO_2 , he thought that by employing hydrates instead of carbonates he might be able to obtain tribasic salts with them also. The Author described minutely the precautions he had taken to insure accurate results, and to overcome the difficulty arising in the case of hydrate of potash from an absorption of oxygen. The boracic acid and hydrates of potash and soda were heated in a silver tray contained in a glass tube through which a current of pure air was passed. The boracic acid and hydrate of baryta were fused together in a silver crucible. It was found that one atom of boracic acid expelled two atoms of water HO from hydrate of potash, and three atoms from the hydrates of soda and baryta. The Author argued that inasmuch as the water of hydrate of baryta was more easily expelled than that of hydrate of soda, and inasmuch as boracic acid drove out no more water from the former than from the latter, it followed that its maximum capacity of saturation was satisfied by the three atoms of base with which it united in each instance. He observed that the formulæ of boracic ether $3\text{EtO} \cdot \text{BO}_3$, and octahedral borax $\text{NaO} \cdot 2\text{HO} \cdot \text{BO}_3 + 3\text{HO} \cdot \text{BO}_3$ were distinctly tribasic. Similar experiments were made with silicic acid, from which it appeared that one atom of SiO_2 drove out $1\frac{1}{2}$ atoms HO from hydrate of potash, and 2 atoms from the hydrates of soda and baryta respectively. Hence, the Author inferred that the capacity for saturation of silicic acid was satisfied by 2 atoms of base, and gave a list of well defined bibasic silicates in illustration. He also referred to the analogies of boracic and silicic acid, and observed that $\frac{1}{2}$ atom of boracic acid might be considered the representative of $\frac{1}{4}$ atom of silicic, whereby the weights of comparable quantities of boron and silicon would be to one another as 3.6 to 7, or as 1 to 2.

Col. YORKE was glad to find that Mr. Bloxam's experiments supported the conclusion at which he had formerly arrived, and which had also been advocated by Dr. Odling, as to the bioxygen formula for silica. Despite Schröder's late experiments, he could find no reason to look upon silica as a tetroxide.

Dr. ODLING said that according to his experiments 1 atom of boracic acid, BO_3 , drove out 3 atoms of CO_2 from carbonate of lithia, and considered that Mr. Bloxam had under-estimated the amount expelled, by a miscalculation of his results. He thought that boron and silicon did not belong to the same group of elements, but rather that they occupied somewhat comparable positions in different groups, and that as sulphur was related to tellurium, phosphorus to bismuth, and silicon to tin, so was boron related to aluminum. Representing 27 parts of aluminum by the symbol Al , we had the following comparable bodies:—

H_3BO_3 Boracic acid cryst.	H_2AlO_3 Alumina gelatinous.
HBO_2 Do. dried at 100°C .	HAlO_2 Diaspore.
MgBO_2 Boracite.	MgAlO_2 Spinel.

Boracite was isomorphous with spinelle, and BO_2 seemed to replace AlO_2 in several siliceous minerals. He considered that the two principal classes of borates were the monobasic, analogous to the metaphosphates, and the tribasic, analogous to the orthophosphates, but that inter-

mediate salts also existed. He preferred to double the atomic weight of silica, and consequently to represent the most highly metallised silicates as tetrabasic.

Professor CRACE CALVERT read a paper "*On the Graphite of Cast Iron.*" He showed that, when cast iron was slowly acted upon by dilute acids, and preferably by acetic acid, a black plumbago-like mass was left, so soft as to be cut with a knife, having a sp. gr. 2.5, and a constant composition. It contained about 80 per cent. iron, 11 per cent. carbon, $2\frac{1}{2}$ per cent. nitrogen, and 6 per cent. silicon. He adverted to the presence of nitrogen in cast iron, and thence inferred that mere nitrogen could not be the differentiating agent between iron and steel.

Mr. DE LA RUE and Mr. WARINGTON referred to the similar change of iron into a soft black substance which took place in an iron grating habitually exposed to the action of sour beer-dregs in a London Brewery. The grating became so soft that it eventually gave way by the mere weight of an empty cask.

The Author of the paper and Messrs. Riley and Malone then took part in a short discussion on the relation of nitrogen to acierification.

CORRESPONDENCE.

The Sale of Poisons.

To the Editor of the CHEMICAL NEWS.

SIR,—The discussion on the prevention of poisoning, caused by accident or otherwise, seems at length to have ended without any practical benefit having been derived from it.

It has been said of railway accidents, that no adequate means will be taken to prevent their recurrence until a Bishop has been sacrificed; the same may be perhaps, but too truly, said of poisoning, that until a Right Hon. Lord or a Right Rev. Prelate has, by ignorance or negligence, accident or design, come to an untimely end, we may look in vain for legislative aid or public interference.

Our own efforts with regard to this important subject are spasmodic in the extreme, chiefly confined to picking to pieces each successive measure as it comes before our Legislature, showing in the most glaring manner its impracticabilities and unreasonable clauses, bringing all our opposition to bear upon it, and ultimately crushing it; and then quietly return to our usual avocations, and gloat over our "success."

Is it not, then, a wonder that with such a perfect knowledge of what we do not want, and what will not be for the benefit of her Majesty's loving subjects; and with an almost unanimous knowledge of what we do want, and what will be for the public benefit, viz., the causing of all future chemists to pass an examination testing their ability and competency, and giving them the exclusive right of vending Poisons, that we do not more strenuously endeavour to obtain it?

These are the only legal restrictions necessary to prevent the recurrence of three-fourths, at least, of the accidents that have occurred, and it would be a guarantee to the public that entering a chemist's shop, that "the right man" would be found in "the right place." Of course I mean in the same way that we are certain that every F.R.C.P. or M.R.C.S. is perfectly competent,—the former to give advice regarding bodily ailments, the latter acquainted with the anatomy of our frame, and able to repair a broken limb or set right a dislocated joint.

To the objection that this would be a work of time, and that it would be no guarantee that those who are at present in business are competent to fulfil the duties required of them, I can only reply that all similar changes have been open to the same objection, and that change for the better is always a work of time.

The sale of poisons may be safely left in the hands of the educated chemist, no legal restriction is necessary with regard to the vending of this or that, for every chemist knows but too well that a summons before a coroner's inquest and a verdict censuring his conduct, is a certain forerunner to a presentation in all due form to the Commissioner of the nearest Court of Bankruptcy, and that he may as well put the shutters up at once. Enter any respectable chemist's shop, ask for two ounces of laudanum, and the intelligent proprietor or his assistant will, in all probability, ask you what it is required for, enquire regarding your knowledge of its properties, dose, &c., and unless the answers are perfectly satisfactory, he will, with the greatest politeness, decline to serve you, and the "word in season" has often, to my knowledge, proved of benefit. In a neighbouring town, a poor woman, a few months since, asked for two-pennyworth of oil of vitriol, and brought a cup to take it in: she was asked what purpose she required it for, and the answer was "her old man was very bad, he had a cough upon him for a long time, and she was told a teaspoonful in water was a very good thing for him,"—of course, she wanted elixir vitriol, which was given, and the proper dose told her; here, in all probability, a life was saved, yet the Humane Society presented no medal; I do not think he was even thanked; and he finds, as nearly all junior members of our fraternity find, quite enough to do to keep the wolf from the door. Innumerable instances of a similar nature may be given, but they are every-day occurrences, as every member of the profession knows.

But the man or woman who contemplates suicide by means of poison, does not procure it from a place questions are likely to be asked with regard to the purpose it is required for; they know full well that laudanum or oxalic acid, and kindred substances, may be obtained from almost any huckster's (whose knowledge does not even extend to the external difference of oxalic acid and Epsom salts, or the varied appearance of tincture of opium and tincture of rhubarb, and whose acquaintance with their properties is even less than that of their appearance), and that he will not be inquisitive, or even trouble himself with labelling the desired article. How often our efforts to prevent suicide are frustrated, the newspapers occasionally tell us; but in the great majority of cases there is an impossibility, from the absence of labels, to find out the vendor. Of course the nearest chemist gets the benefit of the blame: and I do think that, having to bear the blame, he has a right to claim the exclusive sale of the poison.

It would be, I believe, a fallacy to suppose that in a fallible world we can ever attain infallibility, and that as long as there are poisons people will be poisoned, in the same manner that as long as there are razors they will be used for other purposes beside the legitimate one of shaving; but we may reduce them to the minimum, and all suggestions aiming, or tending to attain that desired object, will ever be received and adopted by the majority of chemists.

The bottle invented by Messrs. Savory and Moore, or some practical modification, will prove, when better known, of great service. Labels are a great preventive of error, but labels do not fulfil every requirement, as all chemists know; two bottles were sent out, the one containing hartshorn and oil, the other a mixture, both properly labelled, but of the same size and shape, the hartshorn and oil was given instead of the mixture, the latter being of the same colour and composed of confection of almond, much the same in appearance as the former. In the South of England, a gentleman living in the country, and in the habit of keeping a few simple remedies by him, ordered his servant to take out an aperient draught from the medicine chest; but here again the laudanum was kept in a two-ounce vial, and the black draughts in bottles of the same size and form, and being very similar in appearance, laudanum was, through the carelessness of the man, given

instead of the draught, although the bottles were properly labelled, and the laudanum marked "Poison." The accident being immediately discovered, and proper remedies applied, both cases fortunately recovered.

I could give instances *ad infinitum*, but will conclude with one more for the benefit of those who consider the label a certain preventive of error.

In the suburbs of a neighbouring and one of the largest manufacturing towns there lives a retired minister of one of the numerous Dissenting denominations, who had an only son, who promised to be the solace and support of his aged parents, holding a responsible position in a large metropolitan warehouse. But over-work, bodily and mental combined, with a naturally weak constitution, so much enfeebled him that during the winter of 1859 he was obliged to go home, hoping the rest and purer air of his birthplace would be the means of re-establishing his health. But the work was done; that arch fiend Consumption had struck vitality to its very core. Medical aid was of no avail, except by the help of sedatives to palliate the distressing sufferings. The old man had taken upon himself the duty of administering the medicine at the proper time, and kept the bottles containing the physic on a shelf in an occupied room. Unthinkingly a bottle of bug poison was placed among them by the servant, unknown to the old man, and, like all men arrived at his age, his perceptive faculties were blunted, and so in the dark he poured out a wineglassful of the bug poison, and gave it to his son. The mistake was soon discovered from the odour, naphtha being mixed with the solution of bichloride of mercury, so as to render the taking by accident almost impossible. But the fatal work was done. A constitution weakened by disease was unable to bear the shock, and so he died. A pitiable sight it was to see and hear that old man tell his sad, unvarnished tale before the coroner and his jury, his white hair bleached by the sun of seventy summers, and big tears rolling down his furrowed cheeks; his useless but bitter regrets that any act of his should have hastened, if but for an hour, his son "where all have gone, and all must go." A verdict in accordance with the evidence was given. The bottle was properly labelled "Poison." But I do not think this accident would have occurred if the contents had been placed in a bottle similar in principle to Savory and Moore's.

I am well aware that what I have written has been frequently said before much more ably and more forcibly; but, with the immortal Locke, I think "the pictures drawn in our minds are laid in fading colours, and, if not sometimes refreshed, vanish and disappear." This is strikingly illustrated with regard to the important subject of poisoning. Hoping you will accept this as my apology for troubling you,—I am, &c.

WM. BENNINGTON.

30, Oxford-street, Liverpool.

Magenta Dye.

To the Editor of the CHEMICAL NEWS.

SIR,—Having, till now, overlooked "Magenta's" reply of the 18th May, and as that communication has not altered the opinions I expressed in my last, perhaps "Magenta" would have no objection to make his discovery advantageous to himself, by forwarding me a sample, with quotations, for a quantity, or I should have pleasure in affording "Magenta" every facility for trying it on Coburgs and Orleans on a large scale, and, if found a *bond fide* and practicable article, I need not say the advantage will be great, and no one would have greater pleasure to bear testimony to the fact than—Yours, &c.

JAMES SHARP.

Botterill's Dyeworks, Leeds.

Chemical Notices from Foreign Sources.

I. TECHNICAL CHEMISTRY.

Aich's Metal.—An alloy of iron, copper, and zinc, possessing extraordinary strength is described under this name (*Mittheilungen d. Gewerbever. f. d. Konigr. Hannover*: 1861, s. 59), the inventor being an Austrian marine officer. The specific gravity of the compound is said to be 8.40, but the proportions of the metals are not given. The colour of the metal is darker than brass. It can be worked more easily than iron, and almost as easily as copper. Its ductility is extraordinary, but its most valuable quality is its strength. Tested at the Vienna Arsenal, it was found, when cast, to be nearly as strong as Armstrong gun iron, but by hammering and rolling, its strength was almost doubled. Made into a tube and tested with gunpowder, it was found to have twice the strength of wrought iron, and five times that of bronze gun-metal.

Sterre-metal is another alloy somewhat resembling the foregoing, which it is proposed to use for ships-bolts (it not being acted on by sea-water) engraver's plates, bells, vacuum pans, &c. The composition of this alloy is not given. Both this and the foregoing may deserve the attention of English metallurgists.

Manufacture of Ultramarine.—C. Furstenau gives (*Dingler's Polytech. Journal*, Bd. cliv, s. 63) the following as a good method of making a dark ultramarine. He takes of

Lightly-burnt kaolin	100 parts
Calcined soda	90 "
Refined roll sulphur	100 "
Rosin	6 "
Dry pinewood charcoal	4 "

All these with the exception of the rosin are ground very fine. The rosin is then added in pieces the size of nuts, and the whole is ground together for four hours. The resulting grey powder is then placed in a clay oven and heated quickly to the melting point of an alloy of equal parts of gold and silver. After having been exposed to this heat for five or six hours, the oven is allowed to cool. After a couple of days the bluish-green mass is removed and ground fine in a mill. It is then roasted again in a cast-iron retort, where it assumes the blue colour. It is then finely levigated and dried for sale. The amount of product obtained from the proportions given is 122 of ultramarine.

II. ORGANIC CHEMISTRY.

Myronate of Potash.—Prof. Ludwig and W. Lange extracted this salt from black mustard, by the following modification of Bussy's process. (*Archiv. d. Pharm.* ii. Reihe. Bd. clv. s. 20.) They first extracted the fresh powdered mustard twice with hot alcohol, then treated the powder several times with cold water, evaporated the watery solution on a water bath, extracted the residue with hot dilute spirit of wine, and concentrated the filtered extract. From this the myronate of potash crystallizes out on standing. 500 grammes of mustard yielded one gramme of the salt, the analysis of which gave the formula $\text{KO C}_{20} \text{H}_{19} \text{NS}_2 \text{O}_{18}$, and appeared to be constituted as follows:— $\text{KO S}_2 \text{O}_4$ acid sulphite of potash + $\text{C}_6 \text{H}_5$ + Cy S_2 ; mustard oil, + $\text{C}_{12} \text{H}_{14} \text{O}_4$ sugar; or $\text{KO S}_4 \text{O}_4 \text{H}_2 \text{O}_2$ + $\text{C}_6 \text{H}_5$ Cy cyanide of allyle + $\text{C}_{12} \text{H}_{12} \text{O}_{12}$ sugar.

Myronate of potash boiled with dilute sulphuric acid, the acid being afterwards separated by lime, did not ferment on the addition of yeast. Trommer's test showed, however, the presence of sugar in the solution. When boiled with potash the solution of the myronate turns yellow, evolves ammonia, and, on the addition of hydrochloric acid, sulphuretted hydrogen. Rendered alkaline again, the solution reduces oxide of copper. Caustic

ammonia decomposes myronate of potash, forming a sulphate. Cold baryta water does not act on the myronate, but on boiling the mixture it becomes cloudy, and when hydrochloric acid is added, evolves sulphuretted hydrogen and carbonic acid, sulphate of baryta remaining undissolved. Some of the other reactions of myronate of potash are interesting. For instance, nitrate of silver at first produces no change, but after some minutes the mixture becomes cloudy, and in time a white precipitate falls. On boiling this precipitate dissolves, and sulphide of silver soon separates, a strong smell of the volatile oil of mustard being evolved showing the development of this body from myronate of potash, without the intervention of myrosine. Myronate of potash is easily soluble in water; the clear solution mixed with a colourless solution of myrosine soon becomes cloudy from the separation of sulphur, the smell of the volatile mustard oil being developed.

Composition of Pus.—Giesecke gives (*Ann. d. Chem. und Pharm.*, Bd. cxvii. s. 110) a very complete analysis of what may be called healthy pus. It was thick, pale yellow, faintly alkaline, had the sp. gr. 1022, and no smell. The composition was as follows:—

Water	88.76
Solid matters	11.24
organic matter	10.12
inorganic	1.12

100.00

The solid matter was composed of

4.38	albumen dissolved in pus serum
4.65	pus globules, mucus, with a little leucin and glutin
1.09	cholesterin, with some other neutral fat
0.59	chloride of sodium
0.32	soda (from albuminate of soda), a little phosphate of soda, and a very little sulphate of potash
0.21	phosphate of magnesia, lime, and oxide of iron.

11.24

MISCELLANEOUS.

Chemical Society.—The next meeting of this Society will take place on Thursday next, June 20, when a discourse will be delivered "On the Application of the Induction Coil to Steinheil's Apparatus for Spectrum Analysis," by H. E. Roscoe, Ph.D.

ANSWERS TO CORRESPONDENTS.

Q. S. T.—A notice was given in our first volume of a patent for obtaining a very pure salt of potash in quantity from Sulnit.

J. S.—They will be concluded if possible in the present volume.

P. T. de Tomas.—Consult an elementary work on decimals. 21.4 is a greater number than 21.15. The degree of temperature at which platinum melts is not known: it has been estimated at different times at from 3000° Fahr. to any temperature you like.

S.—In a week or two.

D. Thomas.—We can suggest no plan better than advertising your instruments for sale in our columns.

J. S. Pearson.—They all ultimately find their way to the sea. It will be some years, however, before all the fishes are poisoned, they will last our time.

Ammonia.—1. Liq. Vol. C. C. is generally made by diluting Nq. ammonia with distilled water. 2. We have had no experience in the preparation of spt. ammon. arom. with nutmeg, so cannot say whether it would colour as much as cloves.

The Solar Eclipse.—The following letter from a Correspondent may amuse if it does not instruct our readers:—"I hasten to offer a theory suggested by Professor Faraday's beautiful discourse on the Eclipse of July, 1860. (*CHEMICAL NEWS*, June 1.) The prominence 28,000 miles in length and 74,000 miles above the sun was a planet which struck the embossed surface of the sun and rebounded to that height, where it is now dissolving for the supply of the chromogeneous ether, which is the sun's great atmosphere, enabling him to speed on in his meteoric course, as our own atmosphere enables sound to move."—Kofe."

THE CHEMICAL NEWS.

VOL. III. No. 81.—June 22, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Expansion of Metals and Alloys, by F. CRACE CALVERT, Ph.D., F.R.S., F.C.S., &c., R. JOHNSON, F.C.S., and G. CLIFF LOWE.

(Continued from page 359.)

In order to test the correctness of our estimate of the expansion of the stone upon which some part of the apparatus was placed, we deemed it advisable to submit a specimen of the same stone to direct experiment, and, finding that its expansion exceeded that of several of the metals and alloys, we were induced to make further experiments in the same direction, and found that several minerals had a much greater amount of expansion than had been generally supposed. We are induced, therefore, to give here the results we have arrived at.

Chalk.

10° = 220	90° = 251	10° = 219	90° = 251	10° = 218.5
90° = 251	10° = 219	90° = 251	11° = 218.5	90° = 249.5
31	32	32	32.5	31.0
Mean for 80° = 31.7				
Mean for 100° = 39.6 — 20° correction = 19.6				

Lithographic Stone.

92° = 350	12° = 298	92° = 351
12° = 298	92° = 351	12° = 300
52	53	51
Mean for 80° = 52		
Mean for 100° = 65 — correction 20° = 45.		

Building Stone (Millstone Grit).

91° = 200	91° = 212	91° = 212	11° = 149	91° = 211.5
11° = 135	11° = 149	11° = 149	91° = 211.5	11° = 148.5
65	63	63	64.5	63
Mean for 80° = 63.2				
Mean for 100° = 79.0 — 20° correction = 59.0.				

Stalactite.

99° = 200	99° = 200	16° = 128	99° = 200
16° = 126	16° = 128	99° = 200	16° = 127
74	72	72	73
Mean for 83° = 77.75 (?) 73.0			
Mean for 100° = 87.6 — 20° correction = 67.6.			

Marble (Statuary).

91° = 300	91° = 300	91° = 309
11° = 225	11° = 227	11° = 237
75	73	72
91° = 315	11° = 243	11° = 244
11° = 243	91° = 317	91° = 317
72	74	73
Mean for 80° = 73.1		
Mean for 100° = 91.3 — 20° correction = 71.3.		

These results present two points of interest,—first, the influence which the molecular condition of a substance seems to exert upon its ratio of expansion; thus, between chalk and lithographic stone, on the one hand, and marble on the other, there is a difference of from 100 to 350 per cent.

The increase of expansion of the various carbonates of lime appears to correspond with their increased crystalline condition.

A further instance of this influence we have found in the sulphate of lime.

Plaster of Paris.

99° = 200	99° = 200	99° = 200	99° = 200
16° = 102	16° = 107	16° = 105	16° = 104
98	93	95	96
Mean for 83° = 95.5			
Mean for 100° = 115.0 — 20° correction = 95.			

Lenticular Gypsum.

99° = 350	99° = 350	16° = 240
16° = 235	16° = 240	99° = 348
115	110	108
99° = 348	99° = 350	16° = 247
16° = 245	16° = 247	99° = 350
103	103	103
Mean for 83° = 107		
Mean for 100° = 128.9 — 20° correction = 108.9.		

This influence seems to be general; for, besides the above series, we have drawn attention to it in the body of this paper in reference to the experiments made upon iron, steel, zinc, and the alloys generally.

The second point of interest to which we would draw attention is the high ratio of expansion which these salts of lime possess; for marble and gypsum considerably exceed the expansion of cast iron, steel, antimony and platinum.

We also obtained these unexpected results in the case of rock crystal:—

Rock Crystal.

99° = 250	99° = 250	12° = 163
12° = 158	12° = 163	99° = 250
92	87	87
99° = 250	12° = 163	99° = 251
12° = 164	99° = 250	12° = 163
86	87	88
Mean for 87° = 88.0		
Mean for 100° = 101.2 — correction 20° = 81.2.		

We think it right, before concluding this paper, to give the ratio of expansion of slate and glass, as they have been referred to as being employed by us in determining the amount of correction required to be applied to our mode of conducting the foregoing experiments.

English Tube of Flint Glass (Double Silicate of Potash and Lead).

12° = 200	92° = 264	12° = 198	92° = 261
92° = 264	12° = 198	92° = 261	12° = 195
64	66	63	66
12° = 195	92° = 258	12° = 194	92° = 256
92° = 258	12° = 194	92° = 256	12° = 192
63	64	62	64

Mean for 80° = 64

Mean for 100° = 80° — 20° correction = 60.

French Tubing Glass (Double Silicate of Soda and Lime).

11° = 250	91° = 312	91° = 311	11° = 248
91° = 312	11° = 248	91° = 248	11° = 311
62	64	63	63
91° = 311	11° = 247	91° = 309

Gerhardt's Equivalents and Notation.

ABOUT twelve years ago a distinguished French chemist, Charles Gerhardt,¹ proposed a system of chemical notation differing from that which is in general use. This system, which received at first but little favour, has gradually gained the adhesion of many distinguished scientific men, and is now a subject of general discussion among chemists. What the result of the discussion will be is scarcely to be doubted; but it would have been premature to adopt this system in an elementary exposition of chemistry like the one given in this Manual. Nevertheless, the new system has already acquired such importance that a short outline of Gerhardt's notation, and of some of the most important results which flow from it, will become necessary in this Appendix, the perusal of which is recommended to the reader after he has studied the text of the Manual.

In the new system, as in the old one, the combining numbers are referred to that of hydrogen as unity. The new numbers coincide with those adopted in this Manual, except in the cases of oxygen, sulphur, selenium, tellurium, and carbon. The equivalents of these few elements are doubled, and the symbols representing these double quantities are barred thus,— $\bar{O}$, $\bar{S}$, &c.

The new numbers are chiefly founded on the consideration of the proportion in which the gaseous and gasifiable elements combine by volume.

¹ Extracted by permission from "Fownes' Manual of Chemistry," Eighth Edition.

² "Introduction à l'étude de la Chimie par le Système Unitaire." Par M. Charles Gerhardt. 1848.

Name.	Old Notation.		New Notation.	
	Combining Number.	Symbol.	Combining Number.	Symbol.
Hydrogen . .	1	H	1	H
Oxygen . .	8	O	16	$\bar{O}$
Sulphur . .	16	S	32	$\bar{S}$
Selenium . .	39.5	Se	79	$\bar{Se}$
Tellurium . .	64.2	Te	128.4	$\bar{Te}$
Carbon . .	6	C	12	$\bar{C}$

Gerhardt assumes that equal volumes of the elementary gases and vapours, when compared, under similar conditions of temperature and pressure, contain the same number of atoms. If this hypothesis, which cannot be proved directly, be true, it is obvious that the relative weights of the atoms must be represented by the specific gravities of the elementary gases and vapours. In the following Table the specific gravities of elementary gases and vapours which have been experimentally determined are compared with the atomic weights according to the old and new systems, and, in order to facilitate this comparison, the specific gravities are referred to hydrogen as unity, instead of, as is usually done, to atmospheric air.

Name of Element.	Old Equivalent.	New Equivalent.	Specific gravity referred to Hydrogen as unity.
Hydrogen . .	1	1	1
Oxygen . .	8	16	15.936
Sulphur . .	16	32	31.705
Chlorine . .	35.5	35.5	34.940
Bromine . .	80	80	79.806
Iodine . .	127	127	125.607
Nitrogen . .	14	14	13.969
Phosphorus . .	31	31	63.711
Arsenic . .	75	75	152.792
Mercury . .	100	100	100.555

This Table shows that the specific gravities of the elementary gases and vapours referred to hydrogen as unity represent the atomic weight of these elements. Exceptions, however, are observed in the cases of phosphorus and arsenic, the specific gravities of which are double the atomic weights.

The atomic weights of the gaseous or gasifiable elements, when expressed by the new numbers, yield, with the sole exception of phosphorus and arsenic,² equal volumes of gas or vapour; and if we take the volume occupied by the atomic weight of hydrogen as unity, we may say that the atomic weights of the elements form 1 vol. of gas or vapour. It is supposed that the atomic weights of the other elements, could these elements be conveniently volatilised, would likewise form 1 vol. of vapour.

² There is still some hope that a more elaborate examination of the specific gravities of phosphorus and arsenic may remove this anomaly. This hope is based upon the following considerations:—Earlier experiments had given the specific gravity of sulphur vapour = 95.3, the specific gravity of hydrogen = 1; when the equivalent volume of this element became $\frac{32}{2} = 16$ (or about $\frac{1}{2}$) or $\frac{32}{2.3} = 13.9$ (about 1), according as the old or new equivalent of sulphur be adopted. More recently M. Deville has determined the density of the vapour of sulphur at higher temperatures (at the boiling-points of cadmium and zinc), when a specific gravity was found yielding the equivalent volume $\frac{32}{2.3} = 13.9$, or very little more than 1. Deville has also recently again determined the specific gravities of phosphorus and arsenic, and his observations confirm the numbers given in the text. Nevertheless, on further experiment at still higher temperatures, the anomalies at present observed in the case of phosphorus and arsenic may likewise disappear.

Compounds expressed by the new numbers exhibit a similar constancy of relation between atomic weight and specific gravity, and a similar uniformity in their vapour-volumes.

The specific gravity of a compound in the state of gas or vapour = $\frac{1}{2}$ the atomic weight, or the atomic weights of compounds occupy 2 vols. of vapour.

A few examples will illustrate this point:—

1 atom of hydrogen ($H = 1$ vol.) unites with 1 atom of chlorine ($Cl = 35.5$ vol.), 1 atom of bromine ($Br = 1$ vol.), and one atom of iodine ($I = 1$ vol.).

Combination takes place without any condensation, and the resulting compounds occupy a volume equal to the sum of the volumes of the constituents. It is, therefore, obvious that the atomic weight of hydrochloric acid, HCl , hydrobromic acid, HBr , and hydriodic acid, HI , must each form 2 vols. of vapour, and that their specific gravities must be equal to half their atomic weight.

$$\begin{array}{rcl} H & = & 1 = 1 \text{ vol.} \\ Cl & = & 35.5 = 1 \text{ vol.} \\ \hline H \text{ Cl} & = & 36.5 = 2 \text{ vol.} \end{array}$$

In the compound of hydrogen with oxygen and sulphur, 2 atoms of hydrogen ($H_2 = 2$ vol.) unite respectively with 1 atom of oxygen ($O = 1$ vol.) and 1 atom of sulphur ($S = 1$ vol.). In water and in sulphuretted hydrogen the sum of the volumes of the constituents is 3, but the combination takes place with condensation, the bulk of the constituents (2 vol. of hydrogen and 1 vol. of oxygen = 3 vol.) being reduced to $\frac{3}{2}$ (2 vol.) of water-vapour, or of sulphuretted hydrogen. Here again the atom of water H_2O or of sulphuretted hydrogen, H_2S , yields 2 vols. of gas. The specific gravities of these compounds in the state of vapour are equal to half their atomic weights.

$$\begin{array}{rcl} H_2 & = & 2 = 2 \text{ vol.} \\ O & = & 16 = 1 \text{ vol.} \\ \hline H_2 O & = & 18 = 2 \text{ vol.} \end{array}$$

In the compound of hydrogen with nitrogen, in ammonia, lastly, 3 atoms of hydrogen ($H_2 = 3$ vol.) are united with 1 atom of nitrogen ($N = 1$ vol.). In this case the sum of the volumes of the constituents is 4, but the combination likewise takes place with condensation, the bulk of the constituents (3 vol. of hydrogen and 1 vol. of nitrogen = 4 vol.) being reduced to $\frac{4}{2}$ (2 vol. of ammonia.)

$$\begin{array}{rcl} H_2 & = & 3 = 3 \text{ vol.} \\ N & = & 14 = 1 \text{ vol.} \\ \hline H_2 N & = & 17 = 2 \text{ vol.} \end{array}$$

Thus, we find that, represented in the new system, the atoms of three classes of compounds, as differently constituted as those represented by hydrochloric acid, water, and ammonia all yield 2 vols. of gas or vapour, the specific gravities of these compounds being, consequently, equal to one-half their atomic weights.

(To be continued.)

On Passive Steel, by M. SAINT-EDME.

CONTINUING my researches on the passivity of iron, I found that there exists a difference between the affinity of steel and that of iron for the passive state. I have the honour to present to the Academy the results which led me to this conclusion:—

1. If a steel rod is plunged into ordinary nitric acid (36° Baumé, density 1.34), a rapid and tumultuous boiling takes place round the metal, showing, in the first instance, a very marked action of the acid, but in a very short time—generally less than twenty seconds—the disengagement of gas suddenly ceases and the steel becomes passive. If a rod of iron is placed under the same conditions the action is continuous. This phenomenon takes place with all steels, whether English, German, cast, forged, &c., and the reaction is so decided that it may be considered as a distinctive and unequivocal characteristic of steel.

2. It is a well-known fact that iron wire rendered passive resumes its active condition if made to communicate with a piece of active wire, if both are plunged into the same nitric acid. Several years ago M. Schöenbein noticed that iron wire made passive by immersion in fuming nitric acid had the property of rendering an active piece passive by contact. He could not then account for this variation in the stability of the chemical indifference of iron. The following experiment clears up that which then seemed so puzzling:—Place a rod of steel in ordinary nitric acid, leaving a part above the liquid; the metal becomes passive, as before described; place beside it a rod of iron, which undergoes a continuous action; then, as soon as the two rods are put in communication, by joining the portions above the liquid, or by uniting them in the acid itself, the iron instantaneously becomes passive. Passive steel, then, like platinum, renders iron instantaneously passive.

3. Steel preserves its passiveness under conditions which would entirely destroy that of iron. Iron loses its passiveness when the temperature of the acid reaches 40° C., while a rod of passive steel may remain any length of time in boiling nitric acid without losing its passivity. This experiment has been several times repeated, and is found to be necessary to make the steel passive by contact with cold nitric acid, and then to plunge it in the boiling acid.

4. Iron cannot remain passive in nitric acid containing a certain proportion of hypo-nitric acid. If a galvanic couple is prepared, of which the positive electrode is a rod of passive iron plunged in nitric acid (density 1.34), in about half-an-hour after the circuit is completed the attack on the iron is determined. Under the same circumstances, steel remains passive a longer time, but once a certain point is rapidly reached, it again becomes active.

The passive state is usually explained by the formation of a layer of non-salifiable oxide, which forms electro-chemically on the surface of the metal. It must, then, be admitted that iron, in the state of steel, acquires a greater affinity for nascent oxygen, and that the stratum of non-salifiable oxide which is instantaneously produced on the surface is more adherent, more impermeable to acids, than simple iron. It appears, then, necessary to make a distinction between passive steel and passive iron.—*Comptes-Rendus.*

TECHNICAL CHEMISTRY.

New Theory of Cementation, by M. H. CARON.

THE question I am about to treat is so complex, that I must request the Academy to allow me to establish clearly the facts on which I found my views before I develop them freely.

In a paper which made some sensation, Mr. Sanderson,

an ingenious English manufacturer, concludes,¹ from his experience, that pure and isolated charcoal, oxide of carbon, ammonia, and bicarburetted hydrogen are unsuited for the manufacture of steel; but he shows that iron can be converted into steel by the simultaneous action of ammonia and olefiant gas. After showing that the well known cementation agents, cyanides and ferrocyanides act only by their metalloidal principle, he says:—

1. The transformation of iron into steel only takes place under the combined influence of carbon and nitrogen.
2. If, in analyses of steel, no mention of nitrogen has hitherto been made, the cause of the omission is that the analyses were either ill-done, or that they were made under the influence of a preconceived idea.

May I be permitted to say that Mr. Saunderson has not done justice to his predecessors, Berzelius, Shaffhaütl, Marchand, &c. As a proof, I transcribe an exceedingly judicious note by M. Nickles, Mr. Saunderson's translator:—

"This assertion is not quite correct. There exists a series of analyses of forge iron, cast iron, and steel, attesting the presence of nitrogen in these metals. It is true they do not all contain it, and the greatest quantity that has been found in them is 0.0002 (*Annuaire de Chimie*, 1851, p. 107). These analyses are so much the more reliable since their author, the late M. Marchand, of Halle, experimented from a point of view entirely foreign to the theory of cementation. After it had been established that the titanium of blast furnaces is not a simple body, but a mixture of cyanide and nitride of titanium, M. Marchand surmised the case might be the same with cast iron and steel. Nothing would have pleased him better than to find nitrogen in these carburets, and no one can say that the negative results were obtained under the influence of a preconceived idea. If, then, steel can be considered as free from nitrogen, it is nothing to the purpose that this gaseous metalloidal plays no part in the transformation."

Guided by these trials, which had revealed to me the real part nitrogen plays in cementation, I established, in October, 1860, that one of the most powerful and quickest steeling agents is cyanide of ammonium, a gaseous matter, which, by penetrating to the centre of the iron bars, speedily transforms them into steel of great perfection. And it is remarkable that in every instance of Mr. Saunderson's cementing with hydrocarburetted and ammoniacal gases, he unwittingly produced cyanide of ammonium. The same observation applies to M. Fremy's experiment, who also brought into contact ammonia and carburetted hydrogen, successively, it is true, but under such circumstances that at the moment of reaction the two elements were again found together, and, combining, formed cyanide of ammonium.

It remains for me to prove definitely that whenever iron is converted it is always put into contact with gaseous cyanide of ammonium or with volatile cyanides. This is not a difficult task, since Mr. Saunderson has shown that pure charcoal will not convert, and, according to my own experiments, it is the presence of nitrogen concurrently with the alkali of ashes, and, consequently, the formation of cyanide of potassium, which determines the acieration in the cementation cases.

What, then, is the part these cyanides play? If pure or almost pure charcoal is given to iron,—for example, that of the carburetted hydrogen,—as Mr. Saunderson, M. Fremy, and myself have done, and the operation is conducted at the high temperature generally employed,

the metal becomes too quickly saturated with the carbon, and cast iron only is the result. But if the metal be placed in contact with a carburetted matter, the elements of which are combined in an affinity so close that the iron can only overcome it by prolonged contact, the acieration produced on the surface of the bars will not exceed the desirable limit before the centre of the iron is cemented. On reflecting over this matter, it will be seen that the only undecomposable and volatile combinations of carbon are the alkaline cyanides. Then, cyanides only are the cementing agents, at least, with the temperatures used in manufacture. This restriction is important, as will presently be established.

But a too prolonged contact or too high a temperature will soon modify the effects produced. Thus, cyanide of ammonium, instead of cementing, can transform iron into cast iron,—a fact I have several times verified. It is not so easy to produce this result with cyanide of potassium, because it is less volatile and more difficult to decompose, from which it may be concluded that the most effective agent in acieration should be the least volatile cyanide,—that is to say, cyanide of barium,² a compound which I have already pointed out in another paper. I shall explain more precisely in regard to this substance in another communication on a new cementation process which has been for some months put in practice in a large manufactory in the environs of Paris, by order and at the expense of the Emperor.

All this will become still more clear if it is made apparent that other substances besides cyanides, containing carbon without nitrogen, can convert iron into steel, provided the temperature is not high enough to decompose them, and that their action is not too prolonged. Pure, light carburetted hydrogen gas passed at red-white heat on iron produces not so speedily, but quite as perfect a cementation as cyanides. It is the same with lighting gas,³ which contains a considerable proportion of light carburetted hydrogen gas; and if M. Fremy has been unable to convert iron into steel by means of this agent, it is because he operated at too high a temperature, and protracted too long the contact by the re-agents. Besides, in Berzelius' first edition (vol. iii. p. 279, 1831), there will be found some details on the fabrication of steel by lighting gas, as shown in England by Macintosh. Nevertheless, I agree perfectly with Mr. Saunderson respecting olefiant gas. I have not succeeded in cementing with this gas, though I have operated at the lowest possible temperature, it being too readily decomposed by heat. The tube in which the operation was conducted was found filled with charcoal, and the iron, in spite of tempering, remained soft and malleable.

Strictly speaking, cyanogen is also capable of cementing, but not so well as light carburetted hydrogen gas. These experiments show that to convert iron into steel it is requisite that the cementation agent should be able to carry the charcoal in combination into the pores of the iron when this metal appropriates it in the nascent state. Under no other conditions can cementation be produced.⁴

² Cyanide of barium is easily produced by simply mixing charcoal dust and natural carbonate of baryta. The nitrogen is furnished either by the charcoal itself or by the air which penetrates the sides of the cementation cases.

³ Purified by phosphoric acid and solid potassa.

⁴ On this subject I will remark, that it is impossible to suppose that nitride of iron can be formed at any moment during cementation in manufacturing operations. M. Despretz's nitride of iron has never been produced by any other means than by ammonia, which does not exist in cementation cases; and, even if it did, it would be decomposed by the temperature at which the operation is performed. As to

¹ *Journal de Pharmacie et de Chimie*, 1859, vol. xxxvi. p. 301.

After what I have said, it is useless for me to refer to the existence of nitrogen in steels. My theory is perfectly independent. The quotation from M. Nickles' translation, and the cementations so many, including myself, have effected without the presence of nitrogen, ought, I think, to decide this point. Let it be remembered also that Marchand, in his careful and delicate analyses, could find only such quantities of nitrogen as were either inappreciable or insignificant; that M. Shaffhäutl, the great partisan of the presence of nitrogen in steels, has been obliged to recognise the exactness of Marchand's observations, the same conclusion will naturally be formed as that of this celebrated German chemist,—"If there is any nitrogen it must necessarily belong to the substances mingled with the iron,—substances which no more form an integral part of the metal than does the scoria found with it.—*Comptes-Rendus*.

On the Chemical Composition of Cast Iron and Steel,
by M. FREMY.

(Continued from page 36a.)

I now arrive at one of the most important points in the fabrication of steel. Does there exist, as many metallurgists now admit, native ores containing a body unknown to chemists which would impart their valuable qualities to steel? Shall France be condemned to depend on other countries for the best cemented and cast steels? Can we produce cast irons which, when puddled, will yield steels comparable to those of Germany? Numerous analyses and synthetic operations performed for several years in my laboratory provide me with answers to these different questions.

I know that iron has for certain metalloids preferences excluding other combinations. From synthetic experiments I learn that it is useless to try to give iron an excess of carbon, and to change it into grey cast iron while phosphorus or sulphur remains in combination with the metal. Graphite, the presence of which characterises soft cast iron, appears only after the phosphorus and sulphur have been expelled from the cast iron by means of appropriate purifying agents. And, reciprocally, when grey cast iron is heated in a brasque yielding sulphur or phosphorus it becomes white, and then loses its excess of carbon, which crystallises in large flakes on the surface of the metallic bath.

Silicium only, which, as we know, is allied to carbon by its chemical properties, can simultaneously exist with it in grey cast irons. What I have said of the exclusion of carbon by phosphorus and sulphur applies also to nitrogen. I have found it impossible to make nitrogen react on iron previously impregnated with sulphur or phosphorus. These bodies cannot then assist in cementation; and it is thus intelligible why steel cannot be formed in a blast furnace. The experiments adduced appear to me to imply exactly the conditions of acieration. The best cemented and puddled steels are obtainable only with products almost absolutely pure; nitrogen can only exert its steeling influence on a metal entirely free from silicium, and above all from phosphorus or sulphur.

nitrogen, it is well known that it does not combine directly with iron. The existence of a nitride of iron before the formation of steel is, then, inadmissible; but atmospheric nitrogen, in contact with charcoal and potash of the ashes, yields cyanide of potassium, which is the reason why the presence of this agent in the atmosphere of the cases is absolutely necessary.

* *Journal für praktische Chemie*, v. Erdmann und Marchand.

Many French manufacturers already produce excellent steel, but those who do not yet excel I would urge not to think that certain countries possess exclusively the privilege of making steel of exceptional quality, this perfection being due to the employment of very pure materials. In France we have minerals perfectly suited to the fabrication of steel; but its irons need purifying, and the fabrication of cast iron needs revision. A mixture of iron and cast iron should not be considered as steel. It should not be attempted to convert impure irons into steel, nor should cast irons charged with foreign bodies be refined, for then there is no certainty regarding the stability of the acieration. Such steels easily decompose under the influence of combustible gases, losing their nitrogen and carbon, and returning to the state of iron.

After showing that purity of the metal is an essential condition of the formation and stability of steel, I think it necessary to add that, as has been long since proved practically, the addition of certain metals can improve the quality of certain steels.

Manganese, nickel, titanium, tungsten, &c., are often employed advantageously. These metals, by combining with iron, usefully modify the properties of the steel, yielding true alloys. But I shall presently demonstrate that the metals which appear principally to facilitate acieration are those which, like titanium and tungsten, form with nitrogen fixed compounds.

These special methods of producing steel are perfectly explained, according to my views just set forth; they are included in the general principle which I propounded when commencing my papers on steel. I said, in effect, that steels formed a true family of bodies in which iron is found combined with nitrogenised compounds, capable of containing carbon or other simple bodies.

Theory can now explain the constitution of a large class of steels resulting from these combinations, but practice only can realise their importance.

The effect of manganese, whose influence on acieration is known to all manufacturers, is probably due to its rapid oxidation, thus producing a metallic oxide capable of completing the fining of the iron, and this, by eliminating any foreign body, facilitates the acierating process.

The facts contained in this exposition lead to the following conclusions:—

1. Down to the present time I had established the constitution of steel in proving that this body always contains nitrogen, to be found in the insoluble matter in acids or disengaged by hydrogen. I had proved that steel is easily formed under nitrogenising influence, and that acieration depends on the proportion of nitrogen given to the metal; but I had not yet proved that steel can be restored to the state of iron if its nitrogen is taken away by hydrogen. It is this analytical demonstration that I have placed as the title of this Memoir.

2. In answer to the supporters of the old theory of acieration, who cannot understand how iron can nitrogenise itself in a case apparently containing nothing but carbon, I have proved that in cementation-cases iron can obtain nitrogen not only from the gaseous products circulating in the apparatus, but also from the charcoal, which is always nitrogenised.

3. The undeniable influence of all nitrogenised organic compounds on acieration tends to confirm my theory. I have obtained very active nitrogenised charcoals by previously nitrogenising a ternary organic body, such as sugar.

4. In cementation, nitrogen acts not only chemically,

by combining with carbon to form a sort of cyanuretted compound, which appears to be the essential element of steel, but it exercises a mechanical action in becoming a carburising agent; an excess of carburised gas reduces nitride of iron, and a real phenomenon of substitution is thus produced; nitrogen then plays the part of the shuttle, first combining with the iron, and then making way for carbon, whilst rendering the metal porous. The way in which carbon penetrates iron and the formation of the blisters characterising blistered steel may thus be explained.

5. In the formation of steel by fining cast iron, nitrogenisation is effected at the moment the iron becomes red hot. Nitrogen may be supplied by the cast iron, the combustible gases, and even by atmospheric air.

6. I have proved that the quality of steels does not depend upon the chemical nature of minerals belonging to some privileged locality; it depends entirely on the purity of the iron and cast iron employed. French manufacturers, by purifying their products, may, then, obtain the best steels. My experiments show that, with respect to their combination with iron, certain metalloids have in some sort the rights of precedence. I am convinced that it is impossible to nitrogenise iron when the metal is silicious, phosphoric, or sulphurous. Steel manufacturers will vainly endeavour to produce steel with impure iron or white sulphurous cast iron.

7. The metals appearing to exercise a useful influence on acieration, such as tungsten, are precisely those which form nitrogenised metallic compounds. The different bodies composing the steel family have for their base a nitride of carbon or metallic nitrides.

Thus, laboratory researches and practical observations prove the utility of nitrogen in acieration, and show that steel is not merely a carburet of iron.

The Academy will not misunderstand the direction of my researches; they are, as may be seen, exclusively scientific. It must not be thought that my papers on steel deprive manufacturers who employ cyanides, lighting gas, animal excreta, &c., of the merit of their discoveries. On the contrary, I shall always be happy to acknowledge acierations produced previously to me by nitrogenised bodies. I know too well the ability of our manufacturers not to be persuaded that they will make excellent steels when science demonstrates the constitution of the body they wish to produce. All my efforts have this important object.—*Comptes-Rendus*.

On the Means of Estimating the Value of Gilded and Silvered Articles.

THE following methods have been employed for some time past in the German Revenue Offices for testing the value of gilding and silvering, and may be of interest to our readers from the circumstance that it is often of importance to have a test by which real silver plating on articles manufactured from similarly-coloured metals,—*e. g.*, German silver and Britannia metal, may be distinguished from those, which, to give them a better appearance, are only slightly silvered. The thin coating of silver on this latter class of goods is, of course, soon rubbed off, and then the real colour of the metal becomes apparent.

The value of a test of this kind consists in its easy execution, and the certainty of its indications.

Testing of Gold.—The ordinary method of testing gold by the touchstone is founded upon the insolubility of this metal in nitric acid. If a mark be made on the touchstone with the article under examination, the gold

is not dissolved by this acid, whereas golden-coloured alloys of inferior value are dissolved and disappear immediately.

When articles are very thinly gilded, the detection of the gold in this manner is uncertain, in which case the following method may be used with advantage. This process depends upon the fact that an aqueous solution of chloride of copper is without action on gold, whereas on golden-coloured alloys, as brass, pinchbeck, &c., it produces a black spot. The testing fluid prepared by Loeve's prescription, by dissolving copper in fuming nitric acid and adding a solution of common salt, does not give very certain results, for if the article be but slightly gilded a black spot is nevertheless produced. The concentration of the testing fluid, for instance, exerts a very important influence; for a strong solution of chloride of copper will blacken, although a more dilute form of the same is a reliable test. In order to exclude all traces of aqua regia formed by the action of the nitric acid on the common salt, and which easily dissolves traces of gold, the testing fluid is recommended to be made in the following manner:—

A little carbonate of copper is put into a test-tube, and to this is added, drop by drop, pure hydrochloric acid till the blue powder has dissolved to a clear green fluid, occasionally warming it over a spirit-lamp. This concentrated solution of chloride of copper is diluted for use with from ten to eleven times its volume of distilled water. Before testing, the metallic surface must be well cleaned. This can be done effectually by brushing it for a minute or two with a little spirits of wine, or better, with absolute alcohol.

The surface having dried, a little of the testing fluid is dropped on and allowed to remain in contact for about a minute. The fluid is then removed by means of a small pipette, and the surface of the metal completely dried with bibulous paper; if no dark spot be then visible, the article is coated with pure gold. If the metallic surface is but lightly gilded, a very slight blackening is sometimes remarked, which may throw a doubt upon the result. In such a case, to make quite certain, a little of the surface may be scraped off, and then the testing fluid again applied. If a dark spot is then perceived, the article may be considered as very thinly gilded.

If a further and more direct proof of the presence of gold is required, the article to be examined, or a piece of it, may be put into a porcelain cup, and as much pure nitric acid poured over as will half cover it. The thin layer of gold covering the surface does not prevent the metal from being attacked by the acid, and the gold becoming separated floats in thin films on the top of the liquid. The green metallic solution is now removed, and more nitric acid poured over the gold spangles: it is then somewhat warmed, and water finally added. The gold has now been fully tested by its insolubility in nitric acid, and it only remains to ascertain that it dissolves to a yellow solution in warm aqua regia.

Thin gilding of this description is often met with in the French mock jewellery; the coating is sometimes so thin that it not only deceives the eye, but is difficult to test by the ordinary methods. Instead of putting the entire article into the acid, and thus risking its demolition, a portion of the surface may be scraped off with a knife, and tested with the nitric acid.

When an article appears to be made of massive gold, the testing by means of the touchstone should be first resorted to.

Testing of Silver.—The ordinary and very accurate

method of testing silver is founded upon the insolubility of chloride of silver in dilute acids and in water. This otherwise satisfactory test is, however, difficult to carry out when an article is very thinly plated with silver; but in all these cases a simple and very accurate test can be used, which is based upon the reaction of chromic acid upon metallic silver. For this purpose a testing fluid is prepared by adding pure nitric acid to powdered red chromate of potash, and mixing them in such a manner that a part of the latter remains in suspension, the whole being kept well stirred during the mixing. Equal parts by weight of each may be taken. The nitric must be quite free from hydrochloric acid, and have the proper degree of concentration, being neither too fuming nor too dilute; it should have a specific gravity between 1.20 and 1.25. When the mixture has been prepared for a few hours, and been stirred several times, the reddish-coloured liquid is poured off from the residue and kept in a stoppered bottle. A drop of this liquid is then brought in contact with the metal to be tested, and immediately washed off again with water. If a visible blood-red spot remains, silver is present.

This method requires only the following precautions.—Firstly, the metallic surface must have been quite cleaned from grease or varnish with spirits of wine; Secondly, water must be poured over the treated surface before judging of the colour, as that of the testing fluid is altered by the metal, and the red precipitate is not distinctly visible until the coloured liquid has been washed off. The red spot can afterwards be very easily removed with the finger.

By this method the slightest trace of silver in an alloy may be ascertained. When an article is suspected to be only thinly plated, a very minute drop of the testing fluid should be used. With no other metal or alloy does this red spot, so characteristic of silver, appear; in some cases the testing fluid only corrodes the surface of the metal, whilst in others coloured precipitates are formed, which, however, cannot be confounded with those of silver.

German silver brought into contact with the testing fluid affords no red spot after being washed. The spot will, however, have been strongly corroded.

Britannia metal yields a black spot; zinc is strongly corroded; platinum is not attacked; lead gives a yellow precipitate; tin is strongly affected by the fluid; when the brownish-coloured testing fluid is washed off, a yellow precipitate is perceived, which adheres tightly to the metal; copper is strongly attacked, a tarnished surface of this metal is brightened by the action of the acid. Bismuth yields a yellow precipitate; antimony does not; by this means, therefore, these two metals, somewhat similar in many respects, can easily be distinguished. Mercury, or an amalgamated surface, yields a reddish brown precipitate, which, however, is entirely washed away by the water, and is not likely to be confounded with the silver reaction.—*Deutscher Ingenieur.*

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Ten Lectures on Inorganic Chemistry, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

LECTURE VIII.

Charcoal—Compounds of Carbon with Oxygen—Carbonic Acid.

We have seen that the element Carbon is capable of existing in three distinct conditions; two of them crystalline,

namely, the diamond and graphite, and one of them amorphous, or devoid of crystalline structure, and to which we generally give the name of Charcoal. This latter body, although less interesting in many respects, is to the chemist of more importance than the other two forms of carbon; and to this form we shall have to confine our attention on the present occasion.

We know of several varieties of charcoal obtained from different sources. Animal or vegetable substances when heated to high temperatures, to full redness for instance, in closed vessels such as iron or earthenware retorts, have their volatile constituents driven out of them, and a black mass remains behind, which is this element carbon, associated with more or less of the inorganic impurities which have been present in the organic substance. If we take care to employ an organic substance which is perfectly free from these inorganic impurities, we obtain a perfectly pure specimen of carbon by this process. The carbon prepared in this way, leaving out the very impure form of it which we know as coke, may be divided, perhaps conveniently, into two classes of carbonaceous matters, namely, wood-charcoal and animal-charcoal, which are used for two distinct purposes, and which have, in fact, very different properties. Wood-charcoal is obtained, as its name imports, by the carbonising of wood; wood is heated to redness in closed iron cylinders, or it is sometimes piled in great heaps. The heaps are covered over with turf so as to prevent the access of air to them, and a very slow combustion is carried on until all the volatile constituents are driven off, and a mass remains behind which you all know as wood-charcoal, such as we have here. One of the most prominent properties of this wood-charcoal is its power of absorbing gases. Introduced into different gases, it condenses within its pores a very large amount of some of them. Here we have a table showing the extent of its absorbing power:—

Volume of Different Gases absorbed by one Volume of Charcoal.

Ammonia	90	Bicarburetted hydrogen	35
Hydrochloric acid . . .	85	Carbonic oxide	9.4
Sulphurous acid	65	Oxygen	9.2
Sulphuretted hydrogen	55	Nitrogen	7.5
Nitrous oxide	40	Carburetted hydrogen	5.0
Carbonic acid	35	Hydrogen	1.7

Suppose we were to take a cubic inch of charcoal, then that cubic inch of charcoal would absorb 90 inches of ammoniacal gas. This property of absorbing gases was thought at one time to be the cause of the power that this form of charcoal possesses of depriving putrefying and decaying organic substances of their odour; but Dr. Stenhouse, who has recently investigated this subject, has proved that the power of destroying these noxious odours does not depend, at least wholly, on this property of the charcoal. To this peculiar effect of charcoal I must now direct your special attention.

Charcoal, as we have seen from this table, possesses the property of condensing in its pores a certain amount of oxygen, namely, 9.2 times its volume; and the oxygen which it thus condenses, possesses greater powers of combining chemically at common temperatures, than oxygen under ordinary circumstances, when it is free in the atmosphere. The consequence of this is that when wood charcoal, which has thus been impregnated with oxygen, is brought into contact with combustible substances, especially carbonaceous substances, or compounds of carbon and hydrogen, it actually possesses the power of burning up those substances at ordinary temperature, and effecting their combustion by resolving them into their ultimate products—into the same products, in fact, that we should get by passing these materials through a common fire. This property of thus burning up organic matters passing through the pores of the charcoal, which pores have been previously saturated by oxygen, is of very great im-

portance in the processes of deodorisation and disinfection of atmospheric air. It is only in the dry state that wood charcoal can be successfully employed in this way; when once wetted this power is very materially diminished. We have here a vessel containing in the lower part of it some animal matter—some flesh which has been kept there now for some months, and which is in the most advanced stage of decomposition. It is emitting gases at the present moment of the most intolerable odour, so much so that if they were not completely burnt up before they came out into the room the whole theatre would be rendered quite unbearable from the stench that would be emitted from this decomposing animal matter; and yet if you test the slight odour from the surface of this jar, you will perceive nothing but the most pure ammoniacal odour. Now, what is the process that is going on here? We have a quantity of decomposing animal matter giving off gaseous emanations, which are well known to be very injurious and deleterious to health. These materials, however, have to permeate a layer of some two inches of this roughly crushed charcoal before they can get into the atmosphere. These emanations consist of compounds of carbon, hydrogen, and nitrogen chiefly, though there is also some phosphorus and sulphur present in them; but carbon, hydrogen, and nitrogen, and possibly also oxygen, are the chief ingredients of the emanations. The passage of the gas through the oxygenised pores of this charcoal causes the conversion of the carbon of the noxious gases into carbonic acid, and the hydrogen into water, whilst the nitrogen is transformed, at the same time, chiefly into ammonia, and partly, perhaps, into nitric acid; so that we get the final products of decay, which I have already mentioned as not being noxious. It is only in the intermediate stages that these compounds are noxious. The original flesh before its putrefaction was of course innocuous; and when the elements have finished their oxidation or change and have become converted into their final products—carbonic acid, water, and ammonia—these are also harmless. Now, charcoal finishes, in the course of a few minutes, the process which would take place in the atmosphere in the course of days; so that we get the same effect as if we were passing the noxious substances through a furnace burning brightly, where they would come into contact at a high temperature with atmospheric oxygen. I may possibly be able to show you the ammonia which is passing off from this jar. We can render it visible by a test that I have already applied on a former occasion for rendering this body visible—that of placing above the jar from which it is issuing some dilute hydrochloric acid. You see we have now very copious white vapours produced; I am not sure whether they will be very visible at a distance; perhaps by holding a piece of black paper behind them you may be able to see them. There they are, curling away from the mouth of the jar. White vapours of chloride of ammonium are there being evolved, and they are produced by the ammonia issuing from the jar coming into contact with hydrochloric acid.

Now, this property of charcoal which was first explained by Dr. Stenhouse, has been rendered available, in the first place, for the construction of respirators—charcoal respirators,—some specimens of which I have upon the table. Here is an orinaal respirator which is intended to protect the wearer from the effects of noxious emanations and effluvia. It is intended to be worn in hospitals by nurses who are exposed to contagious and infectious diseases, and under other circumstances of that kind. There are various forms here of these respirators. Charcoal has also been applied to the filtration of atmospheric air in densely-populated districts, where the air is rendered unwholesome by the presence of such noxious emanations. All the air entering a dwelling may be made, by a very simple contrivance, to pass through a charcoal filter, which consists of two surfaces

of perforated zinc, between which there is a layer of coarsely powdered charcoal. The air filters itself through this charcoal in passing inwards towards the dwelling, and in thus being filtered all the organic matter which it contains is burned up by the process we have going on here [referring to the vessel containing the putrefying flesh]. These filters have been used at the Mansion House and Guildhall for several years—four or five years at least. The charcoal never requires changing: it continually renews its supply of oxygen, and continually carries on this process of combustion. You may regard it as a fire which is constantly burning, but does not consume any fuel, or, at all events, all the fuel it consumes is this noxious vapour in the atmosphere; the charcoal itself lasts apparently for ever.

The other form of charcoal—animal charcoal—is used to operate in a similar way upon liquids. It is used for decolorising purposes. It is prepared by carbonising the bones of animals in close vessels—iron retorts, for instance; and we get then a black mass, which, on being reduced to powder, presents the appearance of this specimen before me. Now, here is a decoction of logwood which is very deeply coloured. We will take a portion of it and mix it with some of this animal charcoal. I dare say we shall have sufficient there; and I think if our animal charcoal be good—I have not tried this particular specimen, and the quality varies considerably according to the mode in which it has been manufactured and the material from which it has been prepared; but if the charcoal be good, we shall have, upon filtering this liquid through the filter-paper upon which this charcoal is placed, a perfectly colourless solution passing through. [A portion of the decoction was filtered accordingly.] You see the first few drops of the liquid passing through are a little turbid, by some of the finely powdered charcoal passing through with it; we will first put that back again into the filter. Now you see the liquid is filtering through as clear and colourless as distilled water. On account of this property of decolorising vegetable solutions, animal charcoal is employed for the preparation of organic alkaloids. It is also very extensively employed in the refining of sugar. The syrup being considerably coloured, to begin with, is passed through a thick mass of this animal charcoal; it then comes out almost perfectly colourless, when it only requires evaporation to be converted into crystalline lump sugar of perfect whiteness.

This effect of charcoal in absorbing oxygen is possessed also by other substances, and especially by spongy platinum, which possesses the power to a still greater extent. Here we have a little jet of hydrogen, and here is a particle of this spongy platinum, which is obtained by igniting the ammonio-chloride of platinum so as to leave the metal in a very finely divided state. I will bring this spongy platinum over the jet; you see it begins to ignite; it has ignited our jet of hydrogen. Here you see the platinum is far more potent than the charcoal, and there is no doubt, if we could employ this metal in the same way as charcoal, we should get a much better effect; but this would be impossible on account of the price of the platinum, which is too expensive. There is a greater condensation of oxygen in the pores of the platinum, which causes so rapid an action upon this hydrogen that the temperature rises to the igniting point, and the consequence is the ignition of the jet.

Carbon forms two inorganic compounds with oxygen—namely, carbonic acid and carbonic oxide. The first of these is found in nature both free and combined. It is free in the atmosphere as one of the constituents of the air. Its functions there we shall have to examine, however, in the next lecture, but in this form carbonic acid constitutes only a very small proportion of the atmosphere. A very minute fraction, only about 0.04 per cent. of atmospheric air consists of carbonic acid, but it is calculated that in the total atmosphere surrounding our globe we have no

less than 2,800 billions of pounds of this carbonic acid present. Nevertheless, the great mass of carbonic acid in nature exists in combination, and in combination almost exclusively with lime and magnesia. Those immense lime stone and chalk deposits, and such like strata, which surround us here on every hand consist essentially of one of these bases—lime or magnesia united with carbonic acid, chalk being a carbonate of lime, and carbonate of magnesia being sometimes associated with it. Dolomite, the material with which the new Houses of Parliament are built, is such a solidified form of carbonic acid associated with lime and magnesia.

We can obtain carbonic acid from the air, if we please, by an indirect process similar to that which we employed for the extraction of oxygen from the air. We can cause it to combine with some substance for which it has an affinity, and then extract it from that substance. We take some lime that has been for some length of time exposed to the air—a specimen of old mortar, for instance, which is a material which has been extracting for years this carbonic acid from the air: and from this mortar we can at once obtain a supply of carbonic acid by pouring upon it some strong acid. When we pour hydrochloric acid upon this mortar you see a strong effervescence takes place, caused by the disengagement of the carbonic acid which the mortar has taken up from the air, and which we now extract from the mortar. Carbonic acid is also formed largely during the processes of combustion, respiration, putrefaction, decay, and fermentation. The products of respiration—the breath of animals—passing through any solution which is capable of absorbing carbonic acid reveals the presence of a considerable percentage of this gas. In addition to this source of the gas, we have also a continual production of it in the formation of coal. In the process by which woody fibre is transformed into coal, large quantities of carbonic acid gas are evolved. In volcanic districts, also—in the ancient volcanic districts of the Rhine, for instance—vast quantities of this gas are evolved, and the spring water coming into contact with the carbonic acid saturates itself with it, forming those delicious springs from which the Seltzer water is derived.

None of these processes, however, are readily available for the preparation of carbonic acid for experimental purposes. For such purposes we employ the natural compounds of carbonic acid to which I have just alluded—the carbonates of lime or magnesia, but especially the former. Carbonate of lime, in the form of white marble, constitutes the best material for the production of this gas. If we pour upon white marble some hydrochloric acid it disengages the carbonic acid which was previously in combination with the calcium or lime, and we obtain the latter in combination with chlorine as chloride of calcium; that is, we transform carbonate of lime into chloride of calcium and thus the carbonic acid is evolved. Here is a convenient form of apparatus for the preparation of the gas by this process; in fact it is the apparatus which we have previously described for the preparation of hydrogen. In the place of zinc in our central vessel we have now carbonate of lime or white marble; and the liquid we are employing is dilute hydrochloric acid which comes into contact with the marble in the central vessel. A violent effervescence is the result, the carbonic acid being expelled from the lime by the hydrochloric acid. I can at once get a current of this gas, and can collect it at the pneumatic trough by simply plunging the extremity of this tube beneath the jar. Here is our gas coming off in a continuous stream. As the liquid falls in the upper bulb it rises in the central globe, producing accordingly a continuous stream of gas for a very considerable length of time.

Carbonic acid possesses the following properties:—It is a colourless, transparent, and consequently invisible gas, and vessels filled with it are not distinguishable in

appearance from similar vessels filled with atmospheric air. It possesses a high specific gravity, being rather more than half as heavy again as atmospheric air, its specific gravity being 1.52; and on this account a balloon filled with atmospheric air readily floats in an atmosphere of carbonic acid. We can readily prove this by means of our apparatus. We have here a jar, at the bottom of which is a collodion balloon filled with atmospheric air, and I think you will find that the balloon, which is now resting quietly at the bottom of the jar, will be elevated as the carbonic acid is allowed to pass into the jar. Here is a similar arrangement in this vessel for generating carbonic acid. The gas passing up through this tube will be collected in the jar in which the collodion balloon is resting; and the gradual displacement of the air in the jar by the carbonic acid as it passes in will be rendered evident by the elevation of that collodion balloon. The height of the stratum of carbonic acid will be indicated by the position in which the balloon floats. [A stream of carbonic acid from the generating apparatus was passed into the jar.] You see the balloon is beginning already to manifest some levity, and I think we shall presently have it gradually ascending from the bottom of the jar, and if we continue the supply of carbonic acid we shall bring it up to the mouth of the jar. Carbonic acid possesses a pungent and peculiar odour, and a somewhat acid taste; but is only very slightly acid. It is a very feeble acid, and reddens litmus paper, and manifests an acid reaction only to a very slight extent. It is soluble in water, bulk for bulk, that is, one volume of water will dissolve one volume of carbonic acid at any pressure. If you double the pressure upon the carbonic acid, you reduce the gas to one-half its volume, and the water will then dissolve almost exactly double as much carbonic acid as it did at the lower pressure; thus showing that the water dissolves carbonic acid at all pressures in a volume equal to its own. Therefore, if you reduce your carbonic acid to one-sixth of its volume, you will get six times as much gas dissolved in the water as you would at ordinary atmospheric pressure. Upon this property depend the processes for making those effervescing beverages, such as soda-water, lemonade, and champagne. All these are fluids in which the carbonic acid has been dissolved at higher than ordinary pressures, and on removing the pressure the excess of the gas in the bottle makes its escape, and thus produces that effervescence which we all admire so much in those liquids.

You see our balloon is making some progress upwards; the carbonic acid is now rising in the jar, and as it gradually ascends, the balloon is carried up with it.

Carbonic acid is one of those gases which are capable of being transformed into liquids by exposure either to very intense cold or to great pressure. We were first indebted for this fact in relation to carbonic acid, and a number of other gases, to Professor Faraday, who made a number of very delicate and difficult determinations regarding the pressure required to liquefy many of these gases, and also the temperature required for the solidification of the liquids thus produced. If we take carbonic acid at ordinary temperatures—we will say at the temperature of this theatre—we require to apply to it a pressure of something like sixty atmospheres in order to reduce it to the liquid form, that is, a pressure of something like 900 pounds to the square inch; and, therefore, we require very strong vessels in order to perform this operation. It can, however, be accomplished, and we have here in this vessel a quantity of the liquefied gas under this enormous pressure of 900 pounds to the square inch. It is obtained by compressing the gas by means of a forcing-pump into this cylinder, or it may also be liquefied by disengaging the gas from marble, for instance, by means of a stronger acid in a close vessel, and connecting this vessel then with the cylindrical receiver, so as to distil over the carbonic acid which is produced by the chemical

reaction in the other vessel. The particular specimen of liquefied acid we have here has been obtained simply by pumping into this vessel a large quantity of carbonic acid. Liquefaction was thus effected, and a quantity of liquid acid obtained by this compression. The construction of the iron cylinder is represented in this diagram.

The liquid acid occupies, of course, the lower part of the cylinder, and there passes a tube, nearly to the bottom of the cylinder, and consequently nearly to the bottom of the liquid acid. This tube is closed above by means of a screw. The screw, by means of this lever, can be turned at pleasure, and you will, therefore, see from an inspection of this diagram, that when this screw is elevated a little, so as to allow communication between this exit tube, which is here, and the interior of our cylinder, it will then admit of the passage of the liquid acid upwards through this tube, and outwards into the atmosphere, or into any vessel in which we wish to collect it; so that we have the power of easily transferring the contents of this cylinder into any other vessel, or of letting it freely escape into the atmosphere. Now, if we were to allow it freely to escape into the air we should observe this—that the liquid acid the moment it came into contact with the air produced an enormous volume of carbonic acid gas, but at the same time a solid substance like snow would be produced, and would gradually fall down upon the floor. This snow-like substance is solidified carbonic acid, and it is rendered solid by the loss of heat which is abstracted from the liquid acid in the sudden conversion of this liquid into gas on reducing the pressure. From sixty atmospheres the pressure is thus reduced to one atmosphere; the carbonic acid very greatly expands, enters into violent ebullition, and absorbs a large quantity of heat which it renders latent. The effect of this is to reduce the temperature of the remaining liquid below the solidifying temperature, which is given in this diagram at -135 degrees (*minus* 135 degrees).

Liquefaction and Solidification of Gases.

Name of Gas.	Melting point.	Pressure in atmospheres of Liquefied Gas at 32°F .
Sulphurous acid.	-105°	1.53
Cyanogen.	-30°	2.37
Ammonia.	-103°	4.40
Chlorine.	-103°	8.95
Sulphuretted hydrogen.	-122°	10.00
Protoxide of nitrogen.	-150°	32.00
Hydrochloric acid.	-135°	26.20
Carbonic acid.	-135°	38.50

A temperature of -135 degrees is the solidifying temperature of carbonic acid as determined by Mr. Faraday. This sudden rushing of the gas from the liquid when the latter is relieved of pressure, reduces the temperature of the remainder from 60 degrees down to something like -135 . Now, instead of allowing the liquid to escape into the air, and thus losing the snow-like substance which is produced under the circumstances, we will allow it to escape into this brass box which can be fitted upon the nozzle of

the iron cylinder, and then the liquid will impinge upon a curved strip of brass and make its circuit round this box a number of times. These handles are both hollow, and there is provision made for the passage of the gas through both of them. The gas escaping through these minute apertures is sifted almost completely from the solid particles of carbonic acid, which are deposited within this box where the solid mass finds itself free and under atmospheric pressure. In this way I dare say we shall be able to collect nearly a box full of this solidified carbonic acid. [The small brass box was fixed on the nozzle of the apparatus, and the screw of the cylinder being loosened, the liquid passed into the brass box and afterwards escaped into the atmosphere, a hissing sound resembling the escape of steam through a valve accompanying the passage of the gas.] The liquid is now escaping into the box. There we have an enormous stream of this gas passing into the air, and a little of this snow-like matter escapes with it, and the small vessel becomes so cold that it is covered on the outside with hoar frost. We shall soon have a sufficient amount in the box to assure ourselves of its very low temperature. [After the operation had been continued for a short time the box was detached from the iron cylinder and opened.] Here we have the box very nicely filled with this beautiful solidified carbonic acid. We must not, however, expose it more to the air than is absolutely necessary; we will wrap it up in flannel, not to keep it warm, but to keep it cold. By means of this acid in this solid form we can readily obtain very powerful cooling effects. We can take some of it on the hand, as we shall presently see, without any inconvenience whatever, unless it be squeezed powerfully upon the skin when it produces a very severe burn, or at all events an effect quite similar to that caused by touching red-hot metal. If we dissolve the carbonic acid in a liquid in which it is soluble then that liquid can be applied readily for the production of a very low temperature. The best liquid for this purpose is ether, in which the solidified carbonic acid is very readily soluble. We will place this copper vessel here upon a stool, and beneath it we will place a stratum of water, and we shall see that a little of this acid dissolved in the ether will freeze the vessel to the stool. There you see we can solidify the water beneath this upper vessel which is frozen to the stool immediately. But in addition to this—in addition to the freezing of water—we may solidify other substances which are frozen at a much lower temperature, Mercury, for instance, can be solidified in this way. I will solidify a small quantity first, and perhaps Mr. Adams will, in the meantime, solidify a larger quantity while I am manipulating with this. I want to show you a considerable amount of mercury solidified in this way. [The solidification of a small quantity of mercury was then commenced by the lecturer.] Now our mercury is, I think, perfectly solidified. Yes, there it is a solid mass. The feel of it is exactly like that of red hot iron. Here we will solidify a much larger quantity of this metal, and I will try to show you that when it is thus solidified it possesses malleability; it is capable of being hammered out. We shall not succeed perhaps in getting it hammered into thin plates at this temperature, for it very soon rises in temperature and enters into fusion. This hammer makes the ethereal solution of carbonic acid boil, it is so hot in comparison with the cool contents of this vessel. I will therefore cool the hammer a little so as to have it in good condition for our experiment. We have at the present moment a solid piece of mercury, and we will now see whether we can extend it. [The solidified mercury was then hammered.] You see it is being extended, but it soon begins to fuse; however, before the fusion took place the size of the piece was considerably augmented. Now here [referring to the mercury frozen by Mr. Adams] we have a mass of some four or five pounds of mercury perfectly solid; and I will get Mr. Adams to

hold it in a jar of water elevated here, whilst I throw upon it a ray of electric light so that you may see a very curious effect which is sometimes observed—generally, I may say—when this solidified mercury is suspended in water. [The room was then darkened.] You see the solid mercury is first put into a net-work basket, and then gradually lowered into the water. The effect is, that the comparative warmth of the water will fuse the mercury, and the metal will soon begin to descend in little streams through the gauze; these streams of mercury freeze the water as they pass through it, and form a number of long icicles. There are the little icicles suspended beneath the basket in the water, and the brilliant streams of mercury descending from them. The mercury in melting has frozen a corresponding quantity of water to the solid state. There we have icicles in very considerable quantity, and the mercury is still running out of the mass. [The light was again admitted to the room.] Now we have seen this striking effect, the freezing of fluid mercury which requires a temperature something like *minus* 40° to freeze it; but, really, there is not so much in this experiment as would appear. We have to extract a far less amount of heat from the mercury in order to freeze it than we should have to abstract from the same weight of water to freeze that. It is true we require a lower temperature in one case than in the other; water freezes at 32°, and mercury at *minus* 40°; still I think we shall be able to freeze some of this mercury even in a red hot vessel by means of our powerful refrigerator. Here we have a platinum crucible fixed in this ring (of the retort stand), and we will render the crucible red hot by means of this spirit lamp. We will take a spoonful of mercury for this purpose. We will make our crucible red hot. Now its sides are just heated to redness. [A quantity of solidified carbonic acid was placed in the hot crucible.] I will lower this mercury into the crucible. You see this excessively cold body seems to be very well contented in the red hot vessel; it does not manifest any very extraordinary activity. The fact is, it is not in contact with the vessel at all; there is a stratum of carbonic acid gas surrounding it; and now I will pour a little ether upon it. I believe our mercury is already solidified, but we will make sure of it by giving it somewhat more ether. Now it has solidified. [The edge of a capsule was dipped into the hot crucible, and the frozen mercury was withdrawn and dropped upon a plate as a solid button to the capsule.] Yes, it is now solidified; you see it still adheres to the capsule, but in a moment it will get a little warm around the edges, and I dare say it will drop off. There it is, a solidified mass, which is evidently formed almost with as much ease in this red hot vessel as in an ordinary cold vessel.

Now, if we cast some of this solidified carbonic acid into a jar filled with water, we shall have its gradual disintegration and the formation of the same gaseous carbonic acid as we are disengaging there. We will put some of this solid into a little tin box perforated above, and introduce it beneath one of these jars on the pneumatic trough. There is our carbonic acid, you see, being disengaged from that white solid in a beautiful regular stream; and we will preserve this specimen, for we may possibly require to test it afterwards. The heat of the water is communicated to the solid mass of the acid, which is thereby gasified, and issues through the upper apertures of the box into the jar. We here have a jar rather more than half filled with oxygen, which I think will enable us to see the widely different properties of these two gases in regard to supporting combustion. I will allow some of this gaseous acid to pass up into that jar so as to fill it completely; and as carbonic acid is almost one half heavier than oxygen, I hope here to get a stratum of carbonic acid beneath, and the stratum of oxygen above. We shall have the vessel full in a moment, and then we will remove it from the trough, in order that you may see it better. Now we have what I expected—what will prove to be two strata of gas

in this vessel,—an upper one of oxygen, and a lower one of carbonic acid. The carbonic acid is not capable of supporting combustion under ordinary circumstances; while oxygen, as we are aware, supports it with very great brilliancy. Here we have a brilliant combustion of a taper when held in the upper part of the jar. The taper is extinguished when it descends to the lower part. It is relighted when again brought into the upper stratum of gas. The flame of the taper is extinguished by the carbonic acid in the lower stratum, but the wick remains at a sufficiently high temperature to enable the oxygen in the upper stratum to re-inflame it as soon as it comes in contact with it.

The remaining properties of carbonic acid must be very briefly described. As I have already stated, it is capable of uniting with alkalies, forming salts, which are called carbonates. It is, however, as we have just proved, incapable of supporting combustion, and it is also equally incapable of maintaining animal life. But when we speak of carbonic acid as being incapable of supporting combustion we must receive this announcement with some reservation—with the same kind of reservation with which we received the announcement that protoxide and binoxide of nitrogen were incapable of supporting combustion. We saw that those two gases were capable of supporting the combustion of bodies, the temperature of which was sufficiently high to decompose those gases and convert them into nitrogen and free oxygen. Now, a combustible having a temperature high enough to do this burns in those gases, for it first decomposes them, and then burns in the mixture of oxygen and nitrogen. A similar effect takes place with the carbonic acid. If we have any combustible which burns at a sufficiently high temperature or has sufficient affinity to decompose the carbonic acid, that combustible will then prolong its combustion in the oxygen which it thus supplies to itself. A substance of this kind we have in that powerfully positive metal, potassium, which is capable of burning even in carbonic acid. We will place our potassium in the bulb of this tube. You see we have a stream of the gas coming out there, sufficiently concentrated and pure to extinguish the flame of that spirit-lamp. Now, we require to heat the potassium first before it will ignite, but when we have once got it in a state of perfect fusion it will burn brilliantly in the carbonic acid. There it is burning, you see, in an atmosphere of carbonic acid with a very brilliant light, thus showing that even this gas,—carbonic acid—because it contains oxygen, and because it is capable of decomposition, may be regarded as a supporter of combustion, although we generally look upon it as a type of those gases which possess in a high degree the power of extinguishing combustion.

Weekly Evening Meeting, Friday, March 22, 1861.

*The Rev. JOHN BARLOW, M.A. F.R.S., Vice-President,
in the Chair.*

*On the Origin of the Parallel Roads of Lochaber (Glen Roy),
Scotland, by Professor H. D. ROGERS, F.R.S. F.G.S. &c.*

THE speaker prefaced his account of these curious features in the scenery of Lochaber, by stating that he was induced to recall attention to them from having during four recent visits to the ground, discovered certain phenomena not hitherto noticed or theoretically considered by any of the able and distinguished observers who have preceded him. Though nearly all the more prominent peculiar characters of the scene have been very skilfully described and discussed by Dr. MacCulloch, Sir Thomas Dick Lauder, Charles Darwin, Esq., David Milne Home, Esq., Professor Agassiz, Sir George S. Mackenzie, Robert Chambers, Esq., and others, Professor Rogers has been led by a careful

study of the structure of the so-called Parallel Roads, and a perusal of the views of those eminent geologists, to reject all the hypotheses thus far offered in explanation of the terraces as inadequate, and to recognize in the facts about to be developed, a key to a solution of the problem of their origin, which he thinks may prove satisfactory.

The geographical area of the parallel roads may be defined as embraced between Loch Laggan and Loch Lochy, east of the Great Caledonian Valley. They are chiefly restricted indeed to Glen Spean, Glen Roy, and two or three immediately adjacent smaller glens. One belt of them ranges from near Spean Bridge up the Spean Valley to beyond the head of Loch Laggan; another up Glen Roy to the water-sheds at its very head, and a third through Glen Gluoi to its head.

The "Roads," or Shelves, themselves, are of various heights above the sea, the lowest of the three conspicuous ones in Glen Roy having an elevation of about 850 feet, the middle one a height of about 1060 feet, and the highest a level of nearly 1140 feet. Other much fainter, still more elevated shelves, are discernable in Glen Gluoi, but all hitherto seen lie below a horizon of 1500 feet above the ocean. These Parallel Roads, as they are called, are apparently level, and therefore parallel, but further instrumental measurements are necessary before the question of their absolute horizontality can be regarded as satisfactorily settled.

They constitute a most impressive feature in the scenery of the lonely, treeless glens containing them. Winding into all the recesses and round the shoulders of the mountains which they imprint, they present at first view a striking likeness to a succession of raised beaches deserted by their waters.

Seen in profile, as when looked at horizontally, they resemble so many artificial hill-side cuttings, the back of each terrace lying with the general profile of the mountain slope while the front or outer edge is protuberant beyond it. Each is indeed a nearly level, wide, deep groove, in the easily eroded boulder drift, or diluvium, which to a greater or less thickness everywhere clothes the sides of these mountains. They vary greatly in their relative distinctness, being in some places vaguely discernable, while in other spots they indent the surface very plainly, just as they happen to be narrow and to coincide in slope with the hill, or to be broad and apparently level from front to back. Where most indistinct they are frequently not discernable at all when we stand upon them; though we may in a favourable light have detected their position and course from the opposite side of the glen, or, better still, from the bed of the valley. The conditions which influence this fluctuation in distinctness promise if carefully observed, to dispel much of the obscurity which has hitherto invested the origin of the terraces. The modifying circumstances seem to be all referable to one general condition, that of exposure to a current or inundation, supposed by the speaker to have rushed through these glens from their mouths to their heads, or upper ends. Thus it would appear: 1st, With scarcely an exception, that each terrace or shelf is most deeply imprinted in the hill-side, and is broadest where the surface thus grooved has its aspect down the glen on towards the Atlantic and is faintest where the ground fronts towards the head of the valley on the German Ocean. 2nd, While conspicuous on the open sides and the westward sloping shoulders of the hills, the terraces disappear altogether in the recesses or deeper corries which scollop the flanks of the mountains. 3rd, Each shelf, or "road," grows usually more and more distinct as it approaches the head of its own special glen, until those of the two opposite sides meet in a round spoon-like point.

A fact obviously material to a true theory of the origin of the terraces, is that each of them coincides accurately in level with some water-shed or notch in the hills leading out from its glen into some other glen or valley adjoining,

a coincidence suggestive of the notion that they were formed by the grooving agency of a flood pouring through the glens while it was embayed at the respective levels of these natural waste weirs. In confirmation of this view that they were transiently caused by erosive currents held successively at the heights of the barriers on whose levels the terraces terminate, we have as another interesting general feature, a remarkable ruggedness of the bed of each external glen just outside the water-shed or barrier closing the glen which contains the terrace. These rough and deep ravines, contrasting strikingly with the smooth spoon-like terminations of the terrace-lined glens which head against them, strengthen the suggestion already awakened by the marks of horizontal erosion in the terraces themselves, that the notches or passes which determined the grooving of the hill sides on their one hand were externally the sites of so many stupendous cataracts.

The internal structure or disposition of the matter composing each terrace, affords a further and striking corroboration of this hypothesis of the passage of an erosive flood. It consists in an "oblique lamination," or slant bedding of the constituents of the shelves; viz., the layers of gravel, sand, and other sediment, such as geologists familiarly recognize as the result of a strong current pushing forward the fragmentary material which it is depositing, and which is held by them to indicate in the direction towards which the laminae dip, the direction towards which the current has moved. Now, it is a most suggestive peculiarity in the oblique bedding of these terraces, that the "dip," or downward slant, is almost invariably up the glen, or towards its head, and not down the glen, or towards the Atlantic, as we must suppose it would have been had the glen been a bay of the sea, and these materials but portions of ordinary sea beaches. Indeed, this feature is of itself enough to suggest an origin due to a strong current sweeping inward from the Atlantic, and across the water-shed of the island to the opposite sea.

The speaker next proceeded to examine the hypotheses of his predecessors in this inquiry respecting the origin of the Parallel Roads. They all assume the agency, in one form or another, of standing water, either the ocean in its ordinary state of repose, or lakes pent within the glens.

The notion that a quietly resting sea has fashioned these level shelves is refuted by the fact that they are not true marine beaches; they exhibit none of the distinctive features of genuine sea-shores, not a vestige of any marine organic remains, no rippled sands, no shingle, and no sea cliffs. They display in like manner a total absence of the distinctive marks of lake sides; not one lacustrine organism, neither fresh-water plant, nor animal having ever been discovered imbedded in them. A further difficulty attends the lake-hypothesis in the necessity it imposes of discovering a feasible cause of blockage of the glens at different stations above their mouths, to pond the waters to the respective heights of the terraces. Though much ingenuity has been expended upon this part of the problem no suggestions yet offered of barriers of gravel, accumulated by currents of glaciers from Ben Nevis, can be regarded as admissible, inasmuch as there are no traces of any such in any of those localities where alone we can assume them to have existed to produce the required embaying of the waters. In this entire absence of all remnants of the supposed natural dams across the glens, it is most unphilosophical to take for granted their total obliteration, where no cause has or can be assigned which can have so effaced them.

On the other hand, the hypothesis of successive "sea margins," or sea levels, is overthrown by the now well-established deduction from the speaker's own recent measurements, that none of the several shelves, or "roads," of Glen Roy correspond in level with any of those seen in

the adjacent valley Glen Gluoi, a marked discrepancy separating the two groups of terraces into two independently produced systems. It can be shown, moreover, that these discordances of interval between the shelves of the glens respectively, are such as cannot be accounted for on any supposition of "faults," or dislocation of the earth's crust, in the ground between the two glens. Equally incompatible are all the facts of the relative levels of the shelves, with the notion that they are possibly sea beaches which may have undergone an unequal amount of elevation by an oblique secular rise of the land, such as is known to be very gradually taking place on some coasts at the present day. The individual terraces are too nearly level to admit of this explanation; since so wide a warping of the crust from horizontality within so limited a space as separates the two glens, would have left them conspicuously sloping. Besides, the two systems of shelves are wholly insulated from each other, and the notion of their origin as sea beaches gradually elevated implies a continuity between them, together with certain agreements in their directions of derivation from levelness which we wholly fail to perceive.

In conclusion, the speaker proceeded to sketch the action to which he ascribes the formation of all these shelves, or parallel roads. He supposes the several terraces to have been cut or grooved in the sides of the hills by a great inundation from the Atlantic, engendered by some wide earthquake disturbance of the ocean's bed, and forced against the western slope of Scotland. The features of the country indicate that, while a portion of such a vast sea-tide entering the Firth of Linnhe rushed straight across the island through the deep natural trench, Glen Mor, or the Great Caledonian Valley, a branch current was deflected from this, and turned by the Spean valley and its tributary glens Glen Roy and Glen Gluoi, into the valley of the Spey, and so across to the German Ocean. In this transit, the deflected waters first embayed in these glens, and then filling and pouring through them, would, upon rising to the levels of the successive water-sheds, or low passes, which open a way to the eastern slope of the island, take on a swift current through each notch, and as long as the outpour nearly balanced the influx, this current temporarily stationary in height, would carve or groove the soft "drift," of the hill side. But the influx increasing, the stationary level and grooving power of the surface stream would cease, and would only recommence when the flood rising to the brim of another natural dam a new temporary equilibrium would be established, a new horizontal superficial current set in motion, and a second shelf or terrace begin to be eroded at the higher level. So each of the parallel roads is conceived to have been produced in the successive stages of the rising of one vast steady incursion of the sea. The lapsing back of the waters, unaccompanied by any sharp localized surface currents, through the passes, could imprint no such defined marks on the surface, nor accomplish more than a faint and partial obliteration of the terraces just previously excavated during their incursion. This procedure was elucidated by likening it to what takes place when we allow a steady but gradually increasing jet of water to flow into the tank, perforated laterally with several orifices at successive elevations, the outlets permitting a somewhat less rapid rate of discharge than is equivalent to the influx. If such a tank be smeared internally with soft clay, the inpour can be so regulated in respect to its acceleration, that the water, as it rises successively to the levels of the several orifices will take on a horizontal motion or current, through, first the lower hole, and then the second, and so on, and, remaining approximately stationary for a brief while on the level of each, will groove the soft clay as it passes out, until it swells above the orifice to reach the next. Some such process as this at the notches which terminate the glens will, it is believed, account for the terraces and all the features which belong to them.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Carbonate of Potash.—The amount of water which carbonate of potash contains has been debated by several chemists. Wackenroder, Phillips, Bérard and Giese, and now Dr. J. J. Pohl (*Sitzungsber. d. Akad. der Wissensch. zu Wien.*, bd. xli. s. 630) have severally examined the salt with a view to its determination. The last found in a saturated solution of potash which had been kept in a stoppered bottle for more than a year, some six-sided crystals which, removed into the air, quickly attracted moisture and liquefied. The qualitative analysis of these crystals showed them to be composed of potash, carbonic acid, and water, with mere traces of chlorine and sulphuric acid. When heated to 100° C. they lost 5.180 per cent. of water. Further investigations showed that they contained considerably more water, which could only be expelled by a much higher temperature. The salt dried over sulphuric acid lost, when heated to redness, 15.994 of water, and had the following composition:—

Carbonate of potash	83.517
Water	15.994
Chlorine, sulphuric acid, and loss	0.489
	100.000

This closely approaches the formula $2(KO, CO_2) 3HO$, which would give in a hundred parts carbonate of potash 83.676, water 16.324. As, however, the water expelled above 100° was only 10.814, the author decides that the salt was KO, CO_2, HO and the excess of water hygroscopic moisture. When exposed to the air this salt quickly attracts 4.5 more water, and then has the formula $2(KO, CO_2) 3HO$. By taking up a very small quantity more water the salt liquefies to an oily fluid.

II. ORGANIC CHEMISTRY.

Phenamine.—Phenamine is the name given by Scheurer Kestner (*Polytech. Centralblatt.*, 1861, s. 395) to aniline violet, the composition and constitution of which he has discussed in a review of a work by Willm. In the preparation of his aniline violet the author used hydrochlorate of aniline and chloride of lime. In this process, besides the violet precipitate, a brown colouring matter and a resinous body are produced. The brown matter is present in quantity, and mostly remains in solution. It dyes silk and wool a chestnut brown, and is easily separated from the violet matter in consequence of its solubility in the alkaline liquor. The resinous matter is insoluble in weak spirit, water, and acetic acid, but is easily taken up by pure alcohol, sulphide of carbon, benzole, and ether. With the general properties of aniline violet our readers are well acquainted, and we need not repeat them. When it is dissolved in strong acetic acid, and the solution is allowed to stand for a time, a crystalline crust forms, and the sides of the dish become covered with small crystals. When these are washed free from the acetic acid and dried, they have a greener colour and more lustre than the amorphous mass obtained by evaporating an alcoholic solution. The author analysed both the amorphous mass and the crystals, and obtained the following numbers:—

	Amorphous.		Crystals.	
	I.	II.	I.	II.
Carbon	73.30	74.06	73.58	74.60
Hydrogen	5.96	5.71	6.10	6.10
Nitrogen	11.31	11.46	—	11.92

(The first specimens in both cases were dried at 100°, and the second at 110°.) Aniline violet, therefore, contains less nitrogen than aniline. From the above numbers the author derives the formula $C_{30}H_{14}N_2O_2$ for the crystalline product dried at 110°. The formation of aniline violet

from aniline cannot be satisfactorily explained as long as the composition of the secondary products remains unknown. The author gives the following equation, which represents the change as involving the loss of water and the elements of ammonia:— $5(C_{12}H_9N) + 8O = 2(C_{20}H_{14}N_2O_2) + NH_3 + 4HO$. If this be correct, the change resembles the formation of naphthamein from naphthalidin, whence the author proposes the name phenamein for aniline violet. There is this difficulty, however: ammonia is found in the liquid separated from the precipitated naphthamein, but none can be discovered in that separated from the aniline violet. The author, in the course of his experiments, determined that to change 100 grammes of aniline into aniline violet a quantity of chloride of lime was required which accorded to 12 grammes of oxygen; that is, nearly $1\frac{1}{2}$ equivalents of oxygen to 1 equivalent of aniline.

Alkapton.—Alkapton is the name which Professor Boedecker, of Gottingen (*Annalen der Chem. und Pharm.* bd. cxvii. s. 98), has given to a body he has extracted from urine, which reduces oxide of copper like sugar, but which will not ferment. It may be separated from the urine in the same way as diabetic sugar. When purified and dried, it forms a yellow transparent mass without taste or smell. When mixed with soda lime the author says no ammonia is evolved, but when heated alone in a glass tube an alkaline vapour with a disgusting smell is developed. Alkapton is soluble in alcohol and water, but almost insoluble in pure ether. The yellow aqueous solution reddens litmus. An alkaline solution exposed to the air rapidly absorbs oxygen, and becomes of a dark colour. The other reactions have nothing remarkable. The author, unfortunately, leaves us quite in the dark as to the composition of alkapton.

MISCELLANEOUS.

THE POLYTECHNIC INSTITUTION.

PROBABLY few of our Metropolitan readers know the danger which has threatened this useful institution within the last few months. The important locality in which it is situated and the convenient arrangement of its halls and theatres are too tempting for those whose mission it is to provide the public with a less intellectual kind of amusement; the present Directors have, in fact, only a month or two since, found a competitor for the purchase of the Institution in one of the most extensive projectors of modern music-hall entertainments, and it was for some time a doubtful question as to who would become the proprietor. Science, however, is not yet driven from its popular resort, and, under the energetic management of Mr. J. S. Phené, who has been re-appointed managing director, we hope that the vitality and progress of this Institution will be secured for many years to come. On Saturday last there was a private view of a new gallery of modern paintings which has just been opened. We heartily wish success to this new feature in the Polytechnic Institution, the attractions of which, in an amusing and instructive form, have latterly been of a class to demand public support to a greater extent than, we fear, has been accorded it. We understand it is to be succeeded in the winter by an exhibition of the works of deceased artists. At a meeting of some friends of the Institution, who adjourned after the entertainments to Willis's Rooms, to a cold collation given by the managing director, he pledged himself to raise the credit and usefulness of the Institution to a high pitch, if fairly supported by the public, which he certainly ought to be.

Everything seems now to promise that the Polytechnic will rapidly regain that position in public estimation which it has so long and deservedly enjoyed. We have no reason to imagine that such an institution, under judicious

management, should not become one of the most attractive places of entertainment in the Metropolis. It is quite an error to suppose that the public do not care for science. On the contrary, no subject is capable of exciting more genuine interest, and, if it has the reputation of being dry and difficult to understand, it shows that the expounder has been in fault, not Science herself.

We think, nevertheless, that some improvement might be made in the character of the entertainments offered. For some years they have sadly lacked novelty and variety. We look in vain for illustrations or expositions of the latest discoveries in science; these are seldom introduced to the notice of the frequenters of the Institution until they have ceased to be novelties. Every now and then some startling discovery is made. It attracts considerable interest even amongst the general public, and most literary journals devote a column or two of their space to its popularisation. The gorgeous colouring matters extracted from coal tar, and the recent brilliant spectrum discoveries are instances which at once occur to our minds. It should be the manager's duty to lay wait for such novelties as these and instantly to present them to the public in such a form that their leading features could be readily understood. If, when the interest in these commenced to flag, other more recent discoveries were illustrated in a similar manner, the public would be gradually led to resort to the Polytechnic whenever an important scientific discovery was announced with the certainty of finding it there fully illustrated. The Polytechnic would then be to the middle what the Royal Institution is to the upper classes, and would be patronised in as generous a manner. The lecture on Professor Wheatstone's new Universal Private Telegraph is a step in the right direction, and we hope to see the everlasting diver and diving-bell and the "electric fluid," which is daily "made to assume volumes of beautiful colours," replaced before long by some less hacknied scientific exhibition. The change which has just been effected by the appointment of so enterprising a manager as Mr. Phené will be a good opportunity of getting rid of some of these time-honoured traditions. We shall watch with interest the steps which will, doubtless, be taken by this gentleman to keep up with the progress of scientific discovery.

ANSWERS TO CORRESPONDENTS.

. In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

. All Editorial Communications are to be addressed to Mr. CROOKES, and Advertisements and Business Communications to the PUBLISHERS GRIFFIN, Bohn & Co., at the Office, 10, Stationers' Hall Court, London, E.C.

Vol. II. of the CHEMICAL NEWS, containing a copious Index, is now ready, price 12s., by post, 12s. 8d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vol. I. can still be had, price 10s. 6d., by post 11s. 2d. Vol. III. commenced on January 5, 1861, and will be complete in 26 numbers.

H. Sherman.—Already published.

Kemas.—Received.

M. B., Macclesfield.—Several good formulæ have already been given for black ink.

J. A. D.—Your communication contains nothing new; the first suggestion is impracticable, the second has been accomplished for many years.

J. E.—The specific gravity of pure benzol is 0.885. It boils at 176° F. The specific gravity of the nitric acid used in converting it into nitrobenzol is 1.5. In practice, however, a mixture of strong commercial nitric acid and oil of vitriol is used in equal quantities.

A Subscriber.—1. It is supposed to be loss of water. 2. It has, but not so thoroughly as to decide the points you name. 3. Such analyses could not be done. It requires an experienced analyst with all the resources of a laboratory to detect many adulterations.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Property of Platinum rendered Incandescent by an Electric Current to Produce Gaseous Combinations, by M. E. SAINT-EDMÉ.

I WILL first draw attention to the sensibility of iodised starch paper as a re-agent for oxygen compounds of nitrogen, hyponitric, and nitric acids, infinitely minuter traces of which may be indicated by sensibly blueing the starched paper.

M. Leroux's experiment, which consists in obtaining ozone by passing a current of air on a platinum wire made red-hot by electricity, has led me to inquire whether oxygen only can be modified under the same conditions. I find that pure oxygen passing in contact with a spiral rendered incandescent by an electrical current produces no action on iodised starched paper, and consequently does not appear to be modified. If, on the contrary, oxygen and nitrogen are made to arrive at the same time in contact with the red-hot spiral, the issuing gas colours strongly the iodised starched paper blue, and reddens litmus paper. From this I infer that, under these conditions, nitric acid is formed. I am at present continuing these researches with various gases.—*Comptes-Rendus.*

Transformation of Theobromine into Caffeine, by M. STRECKER.

THEOBROMINE and caffeine are homologues, differing only by C_2H_2 , of which the latter contains the larger amount. M. Strecker has now prepared caffeine artificially, by giving to theobromine the elements it lacked. This was effected by heating the combination formed by theobromine and oxide of silver, in a closed vessel, with methylhydriodic ether. The product, treated with alcohol, yielded crystallizable caffeine in silky threads.

This reaction is easily intelligible by the following formula:—

—*Neues Repert. für Pharmacie*, vol. x. p. 32.

On the Estimation of Aluminium by Standard Solutions, by MM. ERLÉNMEYER and LEWENSTEIN.

By employing a standard solution of ammonia or potassa to estimate the aluminium contained in alum, it has been found that the weaker the alum solution, the more exact is the result; doubtless because the sulphate becomes more basic according to the weakness of the solution. However, as it is impossible to completely avoid the formation of this basic salt, the difficulty is evaded by

transforming the double sulphate into chloride of aluminium by means of chloride of barium.

Potassa, as well as ammonia, entirely decomposes chloride of aluminium, whether neutral or basic. When in this state, aluminium can be estimated easily by standard solutions, and the authors bring forward numerous instances in support of their opinion.—*Zeitschrift für Chem. und Pharm.*

TECHNICAL CHEMISTRY.

On the Employment of Lighting Gas in Acieration, by M. GRUNER.

In the *Comptes-Rendus* of the 11th of last March, M. Fremy put the question to metallurgists whether his experiments relating to the conversion of iron into steel by means of lighting gas could not be practically utilized. In the name of metallurgists, let me be permitted to reply, that practice has long since positively decided this point.

Twenty-five years ago, Mr. Macintosh, an ingenious Glasgow manufacturer, made several tons of cemented steel by submitting iron, at a dull red heat, to the action of lighting gas, operating with from 100 to 150 lbs. at a time, the iron bars being two inches broad and six lines thick. The cementation took from eighteen to twenty hours, and when the operation exceeded that time supercarburization took place.

M. Dufrénoy published these details in the third series of the "Annales des Mines," vol. v. p. 171. He had himself seen specimens of this steel, a portion of which was melted and then worked by the ordinary means. M. Dufrénoy says that the supercarburated thin bars nearly resembled graphite. Thus, then, by the sole action of lighting gas, without mixture of any foreign body, it is possible to obtain either steel or cast iron; it is only a question of time or temperature. To obtain steel there is no need to add ammonia previously in order to nitrogenise the iron. In fact, as M. Caron judiciously remarked, at the meeting of March 18th, coal gas always contains ammonia, and it is not my intention to deny its influence on cementation. I will not further attempt to solve the question of the presence or absence of nitrogen in steel: but it appears to me certain that if nitrogen exists in steel it exists equally in cast iron. Moreover, it is twenty years since Dr. Schafhäütl, of Munich, stated positively that he had found nitrogen in cast iron.

It must be remembered that in ordinary cementation with wood charcoal, as in Mr. Macintosh's experiment, iron is *gradually* brought to the state of steel, and then to that of cast iron. There is no precise limit between these three stages. At what period of the operation, and by what reaction will the nitrogen previously absorbed, again quit the iron? In malleable cast iron,

whence comes the nitrogen if not contained in the cast iron itself? And in puddled steel, how can nitrogen combine with iron or carbon if cast iron does not contain it? I showed in a paper on puddled steel, published a year ago in the "Annales des Mines," vol. xv., that the fining of cast iron in a reverberatory furnace takes place under a coating of slag containing iron and manganese when puddled steel is to be obtained. I ask, then, how the hot atmospheric nitrogen of a furnace can combine with iron and carbon across this coating of scoria? Certainly, if puddled steel contains nitrogen, it can only proceed from cast iron, and it appears to me as interesting to prove its presence in cast iron as in steel itself. But let me be allowed to raise some doubts on the possibility of proving the presence of nitrogen in steel by hydrogen. At red heat iron takes away the nitrogen from ammonia and sets the hydrogen at liberty; and at the same temperature will this hydrogen again take away the nitrogen from the iron,—from the iron which is always in excess relatively to the gaseous molecules which can react on it? It is more difficult to conceive the production of ammonia under these circumstances than the direct combination of hydrogen with free nitrogen.

Another fact which proves that steel and cast iron differ only in containing diverse proportions of the same elements is, that pure white cast irons can be tempered and even forged like steel; witness the white cast iron of Sieges, used for making screw-plates.

Finally, if forged natural steel contains nitrogen, this element ought also to be found in cast iron; and in the second place, it has long been proved that iron can be transformed at will, either into cast iron or steel, by ordinary or coal gas cementation. To effect either, a difference only of time and temperature suffices.—*Comptes-Rendus*.

PHARMACY, TOXICOLOGY, &c.

Note on Blood-stains, by M. GUIBOUT.

ONE of the problems of chemical jurisprudence most frequently presenting itself is that of determining the nature of supposed spots of blood, and one of the most usual methods consists in treating the spots in a manner accurately described in special works with a small quantity of distilled water. This water, in the case supposed, dissolves the colouring matter of the blood, leaving the fibrin on the spot. The liquid, which is red and transparent, loses its colour by boiling, and forms a grey coagulum, which a small quantity of caustic potash will re-dissolve. The liquid, again become transparent, appears either reddish or green, according to the manner of looking at it.

Let us suppose an operation carried on in a straight glass tube closed at one end. The alkaline liquid prepared as is about to be described, will appear green by transmitted light; that is to say, when the tube is placed between the eye and the day light. If, on the contrary, the experimenter stands between the tube and the light, the liquid appears reddish, the colour being perceived from the same side as the reflected rays.

M. Picquot, junior, a pharmacist of Bar-le-Duc, when called upon to decide whether the spots found on some planks in the house of a suspected murderer were spots of blood, after having obtained the preceding results, was much puzzled by reading in M. Devergie's "Médecine Légale" that the sanguineo-alkaline liquid is

green seen by reflection and rose coloured by refraction (vol. iii. p. 822). M. Gaultier, of Claubry, is even more positive. In his "Chimie Légale," p. 7, he says:—"The liquid takes then a green tint seen by reflection and rose by refraction. . . . The green colouration by reflection, rose or reddish by refraction, is a certain proof of the presence of blood." M. Picquot finds here a confusion of words, and I quite agree with him. First, the green colour seen by transmitted light on placing the tube between the eye and the light is evidently not a reflected colour. Again, this same green colour is refracted, since the luminous rays cannot traverse the liquid without undergoing refraction on entering the liquid and again on emerging from it.

Only the reddish colour seen from the side whence the light proceeds simultaneously with the reflected rays can be said to be seen by reflected light; but it must be remarked that it is not reflected directly by the exterior surface of the liquid. It proceeds from all the internal points, undergoes a multitude of internal reflections, and is finally refracted on its exit before reaching the eye.

For the sake of accuracy, it is necessary to substitute in place of the characteristic phrase of MM. Devergie and Gaultier, of Claubry, the following proposition:—The sanguineous liquid (obtained after re-dissolving in caustic potash the coagulum produced by heat), if observed in a straight tube, appears green when placed between the eye and the sun, and reddish if the observer is placed between the sun and the tube.

A straight tube is requisite, because if a flask or any other vessel of a certain diameter is used, the liquid appears rose coloured under all circumstances. If a half-filled flask is shaken the lower portion appears rosy, but the supernatant froth appears green. In a full flask, seen by reflected light, the whole appears rose coloured; when seen by transmitted light the liquid contained in the spherical part of the flask always appears red; whilst that in the straight neck appears green. It is astonishing to observe the same liquid in one part of the vessel appear green and in another part reddish. These variations in no degree invalidate the certainty of the conclusion that no other substance than blood unites the characteristics successively observed in the experiment, namely,—

1. The red colour of the liquid.
2. Its decoloration and coagulation at boiling heat.
3. The grey colour of the coagulum, and its complete solubility in a small quantity of caustic potash.
4. The rose colour of the alkaline coagulum seen by reflected light in a straight glass tube, and its green colour under transmitted light.

5. The distinct and simultaneous appearance of two colours in a small straight-necked flask when the quantity of liquid is large enough to admit of its observation.

All this is without prejudice to the microscopic observation of spots and search for blood globules, which constitute the essential characteristic and most certain indication of the presence of blood.—*Journal de Pharmacie et de Chimie*.

On the Commercial Purification of Bitter Almond Oil, by JOHN S. BLOCKEY.

THE poisonous nature of this substance in its crude state warrants the conclusion that some method of perfectly freeing it from prussic acid or combined cyanogen should be universally adopted, either in its first formation from the almonds or in the subsequent rectification.

Whether even then it is quite harmless is, I think, yet to be proved, and the experiments detailed below tend to show that it possesses very powerful properties, although not so poisonous as the crude oil. Possibly, like many essential oils, it may be found available in medicine. Gerhardt states that the oxide of mercury will free the crude oil from cyanogen, but I have repeatedly tried the efficacy of this agent both alone and with water at various temperatures and during various durations without any success. I also assured myself that the HCy is not in a free state, for no effervescence takes place on the addition of NaO CO₂, either in solution or otherwise. I next tried caustic potassa, but the only effect was to produce a quantity of benzoate of potassa equivalent to the amount of alkali employed. The hydrated oxide of mercury appears to have no action. I concluded, therefore, that some plan must be adopted to free the cyanogen from the oil, which would possess sufficient affinity for that purpose, and at the same time not exert any action on the free hydride of benzoyl. After many attempts, one of which consisted in trying chloride of iron and lime, I finally adopted the following plan. I had found that on mixing a small quantity of oxide of mercury and water, and agitating the oil, and then adding a little caustic potassa and filtering, that the oil passed through clear and colourless and entirely free from cyanogen; but I found that the purified oil dissolves appreciable quantities of the mercury, and if chemically pure hydride of benzole be digested on dry oxide of mercury and filtered it will be found to dissolve it to a certain extent. I therefore procured a wrought iron still having a very long neck, around which a stream of cold water was allowed to pass, so as to cool the vapour sufficiently in order not to crack the glass tubes of the condenser. I found that an ordinary metal worm was speedily dissolved by the distillation of mercury. The pure oil does not dissolve metallic mercury as it does its oxide. In the retort of the still I placed a quantity of crude oil, a small quantity of solution of caustic potassa, and lastly, the quantity of oxide necessary. The actual weight of the latter has to be varied. Some kinds of oil contain more cyanogen than others, and the requisite quantity of oxide was determined on a small quantity and filtration. The quantity of potassa required is, strange to say, very small in all cases, and I always found that, although distillation with HgO and water alone never succeeds in freeing the cyanogen, a small quantity of caustic added produces perfect separation. More alkali must not be added than necessary, or the high heat of the distillation will cause the formation of benzoate; and if the operation be effected by means of a current of steam, the water dissolves large quantities of the oil. For this reason as little water must be added as will suffice to dissolve the caustic alkali, and by careful management of the heat nearly all the water comes over before any oil distils.

Towards the close of the operation, large quantities of a thick smoke suddenly pour over smelling strongly of some of the acryls compounds. I have been unable to determine at present to what these fumes are due, but I have noticed that as the oil distills it gets darker in colour, and at last a tarry matter containing nitrogen comes over, and I have sometimes, by very cautious management, been able to obtain all the pure oil some seconds before the sudden evolution of fumes. The oil then requires filtration from small globules of mercury, and one-tenth of rectified alcohol to be added,—the use of spirit is to prevent the gradual decomposition of the

pure oil, as it becomes turbid and speedily deposits crystals, especially if not perfectly secured from the air. I have never yet had an opportunity of determining the composition of this substance, although I have kept a quantity for some years till an occasion should offer. It sublimes, leaving carbonaceous residue, melts at a low heat, and solidifies again to a crystalline mass.

I intended pursuing this investigation further, but other matters have since occupied me. I should have liked to determine the composition of the tarry residue in the retort, of the acrid vapours, and of these crystals; also to ascertain whether the oil dissolves other oxides, and to what extent. As I cannot foresee any opportunity for so doing for some little time, I am compelled to postpone a paper on these subjects. Meantime, I send the result of some experiments on the effects of the pure and impure oil on the living animal.

Fifteen fluid minims of crude oil administered to a full-grown cat, produced all the poisoning symptoms of prussic acid: violent, spasmodic contractions, &c.; the slightest touch producing a contraction in the limb touched; in twenty-four hours the cat was alive and apparently well.

Twice the above dose killed another cat almost instantly.

Thirty fluid minims of pure oil seemed to act powerfully at first as a stimulant, terminating, after a minute or two, in loss of all power of motion, gradually diminishing, and the animal eventually got well.

The above doses were all administered in olive oil.

Thirty fluid minims of pure oil administered alone killed a cat in some hours.

Ninety minims of pure oil alone killed a cat instantly.

Further experiments suggested themselves, but the destruction of life is not a pleasing subject for experiment, and the above are sufficient to show the poisonous nature even of pure oil, and that this effect is greatly modified by the presence of olive oil.

Heckmondwike, Yorkshire.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Weekly Evening Meeting, Friday, May 17, 1861.

*The Duke of NORTHUMBERLAND, K.G. F.R.S., President,
in the Chair.*

*On the Theory of Three Primary Colours,
by Professor J. CLEEK MAXWELL.*

THE speaker commenced by showing that our power of vision depends entirely on our being able to distinguish the intensity and quality of colours. The forms of visible objects are indicated to us only by differences in colour or brightness between them and surrounding objects. To classify and arrange these colours, to ascertain the physical conditions on which the differences of coloured rays depend, and to trace, as far as we are able, the physiological process by which these different rays excite in us various sensations of colour, we must avail ourselves of the united experience of painters, opticians, and physiologists. The speaker then proceeded to state the results obtained by these three classes of enquirers, to explain their apparent inconsistency by means of Young's Theory of Primary Colours, and to describe the tests to which he had subjected that theory.

Painters have studied the relations of colours, in order to imitate them by means of pigments. As there are only a limited number of coloured substances adapted for painting,

while the number of tints in nature is infinite, painters are obliged to produce the tints they require by mixing their pigments in proper proportions. This leads them to regard these tints as actually compounded of other colours, corresponding to the pure pigments in the mixture. It is found that by using three pigments only, we can produce all colours lying within certain limits of intensity and purity. For instance, if we take carmine (red), chrome yellow, and ultramarine (blue), we get by mixing the carmine and the chrome, all varieties of orange, passing through scarlet to crimson on the one side, and to yellow on the other; by mixing chrome and ultramarine we get all hues of green; and by mixing ultramarine with carmine, we get all hues of purple, from violet to mauve and crimson. Now these are all the strong colours that we ever see or can imagine: all others are like these, only less pure in tint. Our three colours can be mixed so as to form a neutral grey; and if this grey be mixed with any of the hues produced by mixing two colours only, all the tints of that hue will be exhibited, from the pure colour to neutral grey. If we could assume that the colour of a mixture of different kinds of paint is a true mixture of the colours of the pigments, and in the same proportion, then an analysis of colour might be made with the same ease as a chemical analysis of a mixture of substances.

The colour of a mixture of pigments, however, is often very different from a true mixture of the colours of the pure pigments. It is found to depend on the size of the particles, a finely ground pigment producing more effect than one coarsely ground. It has also been shown by Professor Helmholtz, that when light falls on a mixture of pigments, part of it is acted on by one pigment only, and part of it by another; while a third portion is acted on by both pigments in succession before it is sent back to the eye. The two parts reflected directly from the pure pigments enter the eye together, and form a true mixture of colours; but the third portion, which has suffered absorption from both pigments, is often so considerable as to give its own character to the resulting tint. This is the explanation of the green tint produced by mixing most blue and yellow pigments.

In studying the mixture of colours, we must avoid these sources of error, either by mixing the rays of light themselves, or by combining the impressions of colours within the eye by the rotation of coloured papers on a disc.

The speaker then stated what the opticians had discovered about colour. White light, according to Newton, consists of a great number of different kinds of coloured light which can be separated by a prism. Newton divided these into seven classes, but we now recognize many thousand distinct kinds of light in the spectrum, none of which can be shown to be a compound of more elementary rays. If we accept the theory that light is an undulation, then, as there are undulations of every different period from the one end of the spectrum to the other, there are an infinite number of possible kinds of light, no one of which can be regarded as compounded of any others.

Physical optics does not lead us to any theory of three primary colours, but leaves us in possession of an infinite number of pure rays with an infinitely more infinite number of compound beams of light, each containing any proportions of any number of the pure rays.

These beams of light, passing through the transparent parts of the eye, fall on a sensitive membrane, and we become aware of various colours. We know that the colour we see depends on the nature of the light; but the opticians say there are an infinite number of kinds of light; while the painters, and all who pay attention to what they see, tell us that they account for all actual colours by supposing them mixtures of three primary colours.

The speaker then next drew attention to the physiological difficulties in accounting for the perception of colour. Some have supposed that the different kinds of light are

distinguished by the time of their vibration. There are about 447 billions of vibrations of red light in a second; and 577 billions of vibrations of green light in the same time. It is certainly not by any mental process of which we are conscious that we distinguish between these infinitesimal portions of time, and it is difficult to conceive any mechanism by which the vibrations could be counted so that we should become conscious of the results, especially when many rays of different periods of vibration act on the same part of the eye at once.

Besides, all the evidence we have on the nature of nervous action goes to prove that whatever be the nature of the agent which excites a nerve, the sensation will differ only in being more or less acute. By acting on a nerve in various ways, we may produce the faintest sensation or the most violent pain; but if the intensity of the sensation is the same, its quality must be the same.

Now, we may perceive by our eyes a faint red light which may be made stronger and stronger till our eyes are dazzled. We may then perform the same experiment with a green light or a blue light. We shall thus see that our sensation of colour may differ in other ways, besides in being stronger or fainter. The sensation of colour, therefore, cannot be due to one nerve only.

The speaker then proceeded to state the theory of Dr. Thomas Young, as the only theory which completely reconciles these difficulties in accounting for the perception of colour.

Young supposes that the eye is provided with three distinct sets of nervous fibres, each set extending over the whole sensitive surface of the eye. Each of these three systems of nerves, when excited, gives us a different sensation. One of them, which gives us the sensation we call red, is excited most by the red rays, but also by the orange and yellow, and slightly by the violet; another is acted on by the green rays, but also by the orange and yellow and part of the blue; while the third is acted on by the blue and violet rays.

If we could excite one of these sets of nerves without acting on the others, we should have the pure sensation corresponding to that set of nerves. This would be truly a primary colour, whether the nerve were excited by pure or by compound light, or even by the action of pressure or disease.

If such experiments could be made, we should be able to see the primary colours separately, and to describe their appearance by reference to the scale of colours in the spectrum.

But we have no direct consciousness of the contrivances of our own bodies, and we never feel any sensation which is not infinitely complex, so that we can never know directly how many sensations are combined when we see a colour. Still less can we isolate one or more sensations by artificial means, so that in general when a ray enters the eye, though it should be one of the pure rays of the spectrum, it may excite more than one of the three sets of nerves, and thus produce a compound sensation.

The terms simple and compound, therefore, as applied to colour sensation, have by no means the same meaning as they have when applied to a ray of light.

The speaker then stated some of the consequences of Young's theory, and described the tests to which he had subjected it:—

- 1st. There are three primary colours.
- 2nd. Every colour is either a primary colour, or a mixture of primary colours.
- 3rd. Four colours may always be arranged in one of two ways. Either one of them is a mixture of the other three, or a mixture of two of them can be found, identical with a mixture of the other two.
- 4th. These results may be stated in the form of colour-equations, giving the numerical value of the amount of each colour entering into any mixture. By means of the

Colour Top,¹ such equations can be obtained for coloured papers, and they may be obtained with a degree of accuracy showing that the colour-judgment of the eye may be rendered very perfect.

The speaker had tested in this way more than 100 different pigments and mixtures, and had found the results agree with the theory of three primaries in every case. He had also examined all the colours of the spectrum with the same result.

The experiments with pigments do not indicate what colours are to be considered as primary; but experiments on the prismatic spectrum show that all the colours of the spectrum, and therefore all the colours in nature, are equivalent to mixtures of three colours of the spectrum itself, namely, red, green (near the line E), and blue (near the line G). Yellow was found to be a mixture of red and green.

The speaker, assuming red, green, and blue, as primary colours, then exhibited them on a screen by means of three magic lanterns, before which were placed glass troughs containing respectively sulphocyanide of iron, chloride of copper, and ammoniated copper.

A triangle was thus illuminated, so that the pure colours appeared at its angles, while the rest of the triangle contained the various mixtures of the colours as in Young's triangle of colour.

The graduated intensity of the primary colours in different parts of the spectrum was exhibited by three coloured images, which, when superposed on the screen, gave an artificial representation of the spectrum.

Three photographs of a coloured ribbon taken through the three coloured solutions respectively were introduced into the camera, giving images representing the red, the green, and the blue parts separately, as they would be seen by each of Young's three sets of nerves separately. When these were superposed, a coloured image was seen, which, if the red and green images had been as fully photographed as the blue, would have been a truly-coloured image of the ribbon. By finding photographic materials more sensitive to the less refrangible rays, the representation of the colours of objects might be greatly improved.

The speaker then proceeded to exhibit mixtures of the colours of the pure spectrum. Light from the electric lamp was passed through a narrow slit, a lens and a prism, so as to throw a pure spectrum on a screen containing three moveable slits, through which three distinct portions of the spectrum were suffered to pass. These portions were concentrated by a lens on a screen at a distance, forming a large, uniformly coloured image of the prism.

When the whole spectrum was allowed to pass, this image was white, as in Newton's experiment of combining the rays of the spectrum. When portions of the spectrum were allowed to pass through the moveable slits, the image was uniformly illuminated with a mixture of the corresponding colours. In order to see these colours separately, another lens was placed between the moveable slits and the screen. A magnified image of the slits was thus thrown on the screen, each slit showing, by its colour and its breadth, the quality and quantity of the colour which it suffered to pass. Several colours were thus exhibited, first separately, and then in combination. Red and blue for instance, produced purple; red and green produced yellow; blue and yellow produced a pale pink; red, blue, and green produced white; and red and a bluish green near the line F produced a colour which appears very different to different eyes.

The speaker concluded by stating the peculiarities of colour-blind vision, and by showing that the investigation into the theory of colour is truly a physiological inquiry, and that it requires the observations and testimony of persons of every kind in order to discover and explain the various peculiarities of vision.

¹ Described in the Transactions of the Royal Society of Edinburgh, Vol. XXI., and in the *Philosophical Magazine*.

NOTICES OF BOOKS.

A Familiar Introduction to the Study of Polarised Light. By C. WOODWARD, F.R.S., President of the Islington Literary and Scientific Society. Third Edition, carefully revised. London: J. Van Voorst. 1861.

We feel sure that chemists might make more frequent and more serviceable use of the polariscope than they have yet done. When the crystals of the substance under examination can be obtained of sufficient size, sections may often be advantageously used in the experiments, and will frequently afford more information than the confused mass of small crystals obtained by evaporating a drop of the solution on a glass slide under the microscope. In using the microscopic goniometer also the margins of crystals may be conveniently made distinctly visible by the colours which they transmit when viewed in polarized light.

Mr. Woodward's "Familiar Introduction" does not attempt much, but what it attempts it certainly accomplishes. Nothing can be more satisfactory than the way in which the mysteries of this difficult subject are cleared up. The verbal descriptions and illustrations, as well as the diagrams themselves, are easily intelligible to any reader, even to one who approaches the subject for the first time.

Mr. Woodward divides his little work into two parts: the first of these contains an account of the phenomena of polarised light, and the various theories which have been propounded to explain these phenomena; while the second part is devoted to a detailed description of the table polariscope and microscope. These instruments were devised by the author, and are admirably adapted for showing in a conspicuous manner some of the most intricate and beautiful of optical phenomena.

The few remarks on the historical development of this branch of science are interesting, and though brief, serve well as an introduction for the student to the fundamental experiment of Dr. Young on the interference of the waves of light. This experiment is explained with admirable precision and clearness. The next few pages give a very satisfactory view, by means of diagrams and descriptions, of the apparatus by means of which the primary phenomena of waves may be shown. Newton's experimental researches on the cause of the colours of thin plates follows and then the description of the way in which colours are produced by the different lengths of the paths which the rays from grooved surfaces or those which pass through doubly-refracting substances travel. We are thus introduced to polarisation proper. It would not be doing the author justice were we to quote from these sections of his work—the explanations of the various phenomena cannot suffer abbreviation without detriment to their perfection, for not a redundant word is to be found. We can only say to our young readers, and to those who are anxious to have a clear and connected idea of how the various phenomena of polarisation may be satisfactorily explained on the undulatory theory of light, read this third edition of Mr. Woodward's book, studying especially such illustrations as are to be found on pages 29, 30, 31, and 34.

CORRESPONDENCE.

Magenta Powder.

To the Editor of the CHEMICAL NEWS.

SIR,—Practical manufacturers know very well how to prepare a powder which will dissolve freely in the dye-bath, and produce a magnificent shade, either the blue Solferino or red Magenta; and I could now supply solbs. of such a preparation. It is found that dyers will not use it, they prefer a solution of which they can measure a

quantity sufficient for their purpose instead of weighing a powder. There are various methods of producing such preparations—a bright green bronze powder or a red one at about 8os. the lb., which may be diluted in strength and price to any extent, or the pure colour itself may be used. No advantage results in practice from preparing the powder for sale, as it merely saves the expense of spirit, but very little trouble. As to dyeing cotton without a mordant, I cannot discover any means of dyeing that will stand soap—although the mordant does not improve the colour, far from it.—I am, &c. "MARENEST."

"Batopia," June 24.

Transferring the Colours of Marbled Paper.

To the Editor of the CHEMICAL NEWS.

SIR,—I have been experimenting upon paper similar to the enclosed to transfer its colours to other paper and book-edges, but, unfortunately, I am no practical chemist, and have only been able to transfer the reds on the sheet, and that by steeping it in weak, warm soda and water, and afterwards applying a hot iron to it when covered with a wet cloth. Even this changes the colour of it materially, but the blues and other colours will not move. I have seen them transferred quite perfectly, every colour distinct, and believe some acid is employed. I believe there are but two persons in this country who can do it, and they will not part with the secret,—though I think it must be quite simple,—even if paid for it.—I am, &c.

W. LANG.

Sulphuric Acid.

To the Editor of the CHEMICAL NEWS.

SIR,—The writer would feel obliged if any of your readers would inform him if (and where) pure sulphuric acid is to be obtained in quantity,—that is, acid free from lead, arsenic, iron, chlorine, &c. The writer needs a pure acid for certain manufacturing operations wherein even traces of the above foreign matters are injurious.

Can any one inform him of the cause of the universal prevalence of these impurities in the English acid of commerce of the present day? He is informed (but whether correctly so or not he has been unable to determine) that a pure acid, at a moderate cost, is obtainable somewhere on the Continent.

An answer will greatly oblige

A SUBSCRIBER.

MISCELLANEOUS.

Ventilation.—The subject of efficient ventilation of dwelling-houses without creating a draught or admitting dust is a problem of more difficulty than many imagine. It is true that there are several ways of accomplishing this, provided *Paterfamilias* has a long purse and does not object to workmen in his house for several weeks in the year; but to effect the desired end with a trifling expense and without interfering with any present arrangement of the room or building is no easy task. On Saturday last Professor Pepper gave a lecture, at the Marylebone Literary and Scientific Institution, on a novel means of ventilation, illustrating Cooke's patent. After describing experimentally the properties of air, pure and vitiated, hot and cold, and the various plans which had been hitherto devised for replacing foul air by fresh, the lecturer described Cooke's arrangement, by which it is proposed to obtain ventilation in public buildings, dwelling houses, carriages, and ships, without admitting dust or draught. It consists of a series of folds of fine wire gauze, fastened to the top of the upper sash of the window, and made to fold up, so that when the window is closed nothing is seen. When ven-

tilation is required, the top of the window is opened, and the gauze screen comes down as much as is desired, affording means of egress for the vitiated with a gentle influx of pure air. The ventilator may be of two or more folds, of any size or width, and can be readily fixed or detached so as to permit the window sash being opened to the full extent for cleaning or any other purpose. It is simple and inexpensive, excludes dust and dirt, and, the admission of air being imperceptible, may be kept in use with safety in sick rooms and sleeping apartments during the night, when a constant supply of fresh air is mostly required. By its use the inconvenience and danger of admitting currents or draughts of air is entirely avoided.

Conversations at Bath House.—On Wednesday, the 20th inst., Lord Ashburton held a scientific conversation at his town residence, Bath House, Piccadilly, which was numerous and very fashionably attended. Among other scientific instruments which were collected together and experiments shown, Mr. Darker contributed an apparatus illustrating several points in the beautiful phenomena of the polarisation of light. Messrs. Powell and Lealand, Smith and Beck, and Baker exhibited several binocular microscopes, under which, among other objects, were seen the "volvox globata," the circulation of the blood in the branchiae of the newt, and the circulation of the sap in *Valeriana*. Among other inventions shown were Professor Wheatstone's new printing telegraph, and wave machine, for explaining the theory of the undulations of light, the *Bulldog* deep sea sounding machine, and Johnson's sounding apparatus and thermometer. Some large articles in aluminium attracted much attention, especially an elaborately-ornamented helmet, which, though massive in appearance, scarcely exceeded in weight that of an ordinary hat. Messrs. Spencer Browning and Co. exhibited their new spectroscope, for the purpose of analysis by light, and during the evening exhibited the various spectra of barium, strontium, calcium, potassium, lithium, and sodium, and also, by means of an adjusting prism, showed the spectra of barium and lithium, in the field of view of one of the instruments at the same time for the purpose of comparison. Three different sizes of the instrument were exhibited, the smallest, which is intended for tourists, when closed being capable of packing in a morocco case, the outside dimensions of which were five inches by four and three-quarter inches, the thickness being only one and a-half inches. Even with this small instrument the sodium line D could be distinctly seen double. The portability and efficiency of the apparatus were highly commended by all who inspected it. Mr. Ladd also exhibited spectrum apparatus, and Messrs. Elliott Brothers some interesting experiments in the diffraction of light by means of the oxyhydrogen lime light.

ANSWERS TO CORRESPONDENTS.

*. In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Gleason—Outlines of Analysis.—We do not know the publisher of this work. A London bookseller could doubtless get it for you.

E. J. Rutter.—Received with thanks.

A. D. M. D.—No letters have yet arrived. We will forward any that come.

F. Chadwick.—No such maps are published in this country. A few metals only have been copied.

C. Eades.—We will gladly insert the practical hints you suggest. Will you forward those which you say you could give? and we will insert others as soon as they can be obtained.

Books Received.—"Dictionnaire de Chimie Industrielle," par MM. Barreuil et Aimé Girard. Introduction and first volume. Paris: Dezobry, E. Magdeleine et Cie., 78, Rue des Ecoles. "On Poisons and the best Means for Preventing Accidents," in connection with the patent safeguard bottles originated by Messrs. Savory and Moore.

 Molesworth, W. N. on the origin of species, 10
 Molybdate of ammonia a test for sulphur, 192, 204
 Molybdic acid, 223
 Mordanted cloth, cleansing before dyeing, 183
 Morsehead, Captain, on the New Zealand iron sand, 300
 Mosley, Mr. meteorological observations 124
 Mourier and Vallant, M.M. a new alloy of copper, 269
 Mohr's metamorphia, 159
 Mucklow, E. improvements in the treatment of madder roots munjeet, or other plants of a similar class, 125
 Mulder, M. test for grape sugar, 324
 Müller, H. and W. De la Rue, on the action of dilute nitric acid upon some hydrocarbons of the benzol series, 165
 Dr. John, on santonate of protoxide of mercury, 56
 Mushelt, Mr. on the New Zealand iron sand, 300
 Musk, 27
 Muspratt, Dr. copper in mineral waters, 251
 molybdate of ammonia a test for sulphur, 204
 Mustard, adulteration of, 855
 Myronate of potash, 370
 NAPHTHALIC alizarine, 330, 356
 Naphthaline, coloured derivatives of, 327, 329, 361
 Naphthamine, 339
 Natural oxide of silver, 214, 242, 268
 Negative oxygen, 98
 Neger and Kypke on new hydro-selenocyanides, 269
 Nicholson, E. C. improvements in the production of colours for dyeing and printing, 78
 Nickel, carbonate of, 135
 oxamate of, 258
 Ninaphthalamine, 259
 Nitrate of aniline, action of heat on, 271
 of potash and soda, improvements in the manufacture or production of, 289
 Nitrates and ammonia, comparative action of, on vegetation 341
 into ultimates, transformation of, 341
 Nitric acid, action of on hydrocarbons, 165
 and hydrochloric acids with soda and potash, 81
 Nitride of iron, 297
 Nitrile of leucic acid 176
 Nitrobenzine, new acid by oxidation of, 297
 Nitrophenylene-diamine, 350
 Nitro-prusside of sodium as a re-agent, 21, 29
 Nitrosophthaline, 352
 Nitrosophenylene, 350
 Nitrous acid, action of on cuprous oxide, 253
 Noed, Dr. analysis of the saline water of Purton, near Swindon, North Wilts, 77
 Noeliner, alloy of tin and iron, 14
 Notation, chemical, 111
 and equivalents, Gerhardt's, 372
 Numerical relations between equivalents, 97
 ODLING, Dr. the adulteration of food, 240
 an account of Guy's Hospital well, 35, 49
 Oil, castor, in volatile oils, 42
 of geranium, 254
 of turpentine, on the action of sodium on, 159
 produced from coal, 342
 commercial purification of bitter almond, 386
 Ointment, iodine, 172
 spermaceti, 173
 Olefins, on some derivatives from the, 248
 O'Neill, Mr. O. on changes of density which take place in rolled copper by hammering and annealing, 174
 Oppenheim, Dr. on nitro-prusside of sodium as a re-agent, 21, 29
 on the separation of tellurium from selenium and sulphur, 29, 34
 Organic compounds, on the elementary analysis of, 67
 Osborn, H. M.D. lead in the calcareous deposits of kettles, 41
 Oudemans, M. solid acids of cocoa butter, 358
 Oxalate of ammonia upon the precipitation of Prussian blue, effects of, 95
 of iron, 48, 369
 Oxamic acid, salts of, 258
 Oxen, sheep, and pigs, composition of, 296, 326
 Oxide of bismuth and solutions of sesquioxides, 147
 of chromium, 224
 and salts of iron and salts of the fixed alkalis, 221
 of lead, preparation of, free from copper and iron, 183
 of silver, natural, 214, 242, 268
 action of sulphurous acid on, 282
 Oxygen, action of, on perchloride of phosphorus, 47
 on aniline, on the action of, 98
 cost of, by different methods, 192
 positive, negative, and neutral, 98
 reactions of, 253
 Oxy-ethers, ethylamine produced from, 85
 PAPER-HANGINGS, arsenical, 210, 372
 Paper, mineral adulterations in, 329
 Paraffin, the economic history of, 219, 281
 Parchment paper, 16, 370
 Paridin, 128
 Paris blue, 259, 349

VOL. IV. No. 83.—July 6, 1861.

CHEMISTRY OF THE COMET.

PROBABLY few of our readers are ignorant that a most brilliant member of this erratic celestial family is now a conspicuous object in the northern heavens. It first made its appearance on Sunday evening last, after sunset, when, as the clouds cleared away, it was suddenly discovered shining as bright as a star of the first magnitude, and almost rivalling the magnificent comet of 1858 in brilliancy and development of tail, whilst it far surpassed it in the diameter of nucleus.

An opportunity which perhaps may never occur again is thus allowed for physicists to become acquainted with the intimate constitution of these mysterious visitors. On the occasion of the last appearance of so brilliant an object, in 1858, philosophers could do little more than examine it through their telescopes, and wonder, and speculate on its constitution. Since then, however, science has made rapid strides, and we are at the present time in possession of methods of analysis vastly more searching and powerful than any known previously. Chemists can now analyse, in the most rapid and accurate manner, almost everything which is visible to the human eye. It matters not whether the body possesses a tangible substance or not, whether it is close at hand in a test-tube or millions of miles away; if it only fulfils the one condition of emitting light, it is almost certain to reveal the secrets of its composition when submitted to the new development of *spectrum analysis*.

The actual metallic constitution of the sun has already been shown by this means; that of the fixed stars is likewise being ascertained in the same manner, and we really hope that the present opportunity will not be allowed to pass without the beautiful method of spectrum analysis being applied to determine the elementary constitution of cometary bodies. The apparatus required would not be more than is already in the hands of many scientific men. A large telescope, equatorially mounted, would, from some experiments of our own upon this subject, seem to be necessary, in order to obtain sufficient light to illuminate the field of view. The spectrum apparatus being placed in proper adjustment, the luminous image only requires to fall on the slit and along the axis of the collimating tube for the fixed lines in the cometic spectrum to be instantly visible. A small and temporary arrangement, hurriedly fitted up, has been sufficient to satisfy us of the existence of fixed lines in the spectrum of the light emitted from the comet at present visible, but they were too faint to admit of identification. This experiment should at once be repeated with larger and more powerful apparatus. Many important questions would thus be finally settled. If the comet shone merely by reflected light from the sun, the ordinary solar fixed lines would be the only ones visible. If, however, as is most probable, some of its splendour is due to native light, the spectrum would as readily reveal whether the nucleus or the tail were in the solid or vaporous state;

if the former, it would give a continuous spectrum, whilst if it were a vapour, the spectrum would be disconnected, and the new lines in it would at once disclose the elementary bodies to which they were due. It is, however, impossible to foresee all the valuable information on the obscure subject of stellar chemistry which could in this manner be obtained. We trust that, having pointed out this most promising field of observation, the rich harvest of facts with which science can thereby be enriched will not be allowed to escape for want of able observers.

WATER *versus* FIRE.

THE natural antagonism of fire and water is so deeply rooted a matter of popular belief that were it not for the striking illustration to the contrary exhibited by the recent gigantic conflagration near London-bridge, we should scarcely venture to raise a doubt on this point. A visit which we paid to the burning ruins soon after the outbreak, and some observations which we made on that occasion while accompanying the firemen as near as could be ventured to the blazing mass, have, however, served to confirm our previous impressions in a remarkable manner.

The action of water in quenching fire is principally due to two causes. One is its great capacity for heat, a property which enables it to exercise a considerable cooling influence upon any burning body. The other is its fluidity, enabling it to run over the surface and penetrate the pores of a combustible body, acting the part of a varnish, sealing it up from contact with the atmospheric oxygen, and thereby stopping combustion. In the case of water supplied from a fire engine, the mechanical force with which it impinges upon the burning body may likewise have some beneficial effect, actually beating out the fire as if with a stick. It will however be seen, that unless the volume of water thrown on to a fire be very large indeed in proportion to the bulk of that fire it can do but little good; and if it be very small in comparison to the amount of burning material, it is positively injurious, acting the part of additional fuel to the flames.

Every chemist knows what takes place if a small quantity of water is projected into the midst of a large mass of red hot combustible matter. It is decomposed in presence of the carbon into carbonic oxide and hydrogen, each highly combustible gases, and thereby tending to increase the volume of flame. This we are satisfied was the case with a large proportion of the water which was thrown on during the first few days of this memorable fire. Standing inside the gates of Cotton's Wharf we watched a jet of water from the powerful steam fire-engine, as the firemen directed it into a brightly burning mass of combustible matter. The liquid hissed and vaporised the instant it touched the incandescent matter on which it was directed; but in this and in most other instances where water was

directed into the fiercest parts of the fire, the supply of heat from combustion was so much in excess of the loss of heat required to vaporise the water, that, except at the spot on which the solid jet of liquid fell, there was scarcely any appearance of deadening or quenching, and as soon as the hose was directed towards another part of the blazing mass, the spot on which the water had been previously falling glowed as brightly as ever.

The supply of water, however, had not only a negative action, in some cases it did positive injury; for after falling into the brightly glowing fuel and becoming at once vaporised, it rose through the thick masses of red hot combustible matter, and there underwent decomposition. To a careful observer the result could be seen in the form of an increased vigour in the tongues of flame, which rose and licked the neighbouring walls with renewed violence. We were curious to see if this decomposition and subsequent recombustion of the water could be rendered visible, and on a subsequent occasion examined the flames by means of a small pocket spectroscope. A portion of the ruins was chosen which still blazed with almost its original fierceness, and on which a stream or two of water was being pumped. The spectroscope was at first turned towards a portion of the flames where there was no water; as might be expected the spectrum was quite continuous; a faint glimmer only of the yellow soda line being occasionally visible; but upon the men directing their hose upon this portion, the yellow line instantly shot across the field of view with great splendour, and remained there during the whole time the water was being poured into the burning mass. We subsequently found that the presence of this line offered an easy means of telling whether water was being poured into any portions of the burning ruins. Where water was absent the line was only occasionally visible, whilst whenever water was added to the flames it appeared with considerable brightness, projected across the continuous spectrum.

Now, we submit that this is a good (though indirect) proof that the water had suffered decomposition, and that some portion of the flames which were towering towards the sky consisted of the burning elements of this identical water, which thus acted the part of fuel to the fire. The great difficulty of preparing "water gas," even in the laboratory, so as not to burn with a yellow flame, is well known, and it is therefore unlikely that when formed under circumstances eminently suitable for the production of the yellow soda flame, this should not be present in considerable quantity.

Another point that struck us most forcibly when watching the firemen with their hose, was the utter absurdity of the attempt to produce any effect upon so stupendous a conflagration with such an insignificant jet of water. Three acres of combustible matter were blazing and roaring like a blast furnace, and just at the outskirts of the burning heap a few thin streams of water were being sprinkled on, producing about as beneficial an effect as if a child had taken a penny squirt to it, not even wetting it so much as a heavy shower of rain would have done. It is scarcely part of our province to suggest an improvement on this state of things. To place a floating fire-engine on the Thames capable of raising any number of tons of water per minute, and deluging an incipient fire in so perfect a manner that further outbreak would be impossible, seems a not very difficult problem, although it is one for mechanicians rather than chemists. Like all other difficulties now-a-days, the only question requiring answer is, "How

much will it cost?" and whatever that might be, it could not possibly come up to what the Insurance Offices will have to pay for this one fire.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Colour-tests for Strychnia and the Diagnosis of the Alkaloids, by WILLIAM A. GUY, M.B. Cantab., Fellow of the College, and Professor of Forensic Medicine, King's College, London.

(Continued from vol. III. p. 303.)

I NOW proceed to discuss the third of the four questions propounded in my first communication, namely, Are the colour-tests, or is the selected test, open to any serious objection?

Of chemical tests in general, it may be said that they are more or less liable to the following objections or disparagements:—1. They may be wanting in delicacy; that is to say, they may not be able to detect minute quantities of the substances to which they are applied as tests. 2. They may be wanting in certainty; in other words, they may fail from slight causes difficult to appreciate and define, such as the quantity or proportion in which they are applied, or the strength of their solutions if used in the form of liquid. 3. They may give rise to transient effects, or to appearances difficult to describe or define. 4. They may be unusually liable to failure from impurities in themselves, or in the matters to which they are applied as tests. And, lastly, they may produce of themselves appearances nearly allied to those which they occasion when added to the matters under examination.

From the first of these objections all the colour-tests for strychnia are certainly free. They are able to detect very minute quantities of the poison. From the fourth objection, too, as it will presently be shown, they are at least as free as the majority of chemical tests. To the second, third, and last objections they are certainly exposed, but under what circumstances and in what degree, it will be necessary to inquire.

The occasional failure of the colour-tests for strychnia from slight and obscure causes is not to be denied. It is proved by the experiments already detailed, and is admitted by all experienced chemists. But it should be understood that this objection has only a limited application. It goes only to the extent of impairing the value of the evidence derived from a negative result. If the colour-tests fail when applied to a spot acted on by sulphuric acid, their failure is not conclusive evidence of the absence of the poison. It affords a strong probability of such absence, but nothing more.

The reactions of the colour-tests for strychnia are certainly transient. They are not like the permanent white, crystalline, or coloured precipitates afforded by most chemical tests. But the objection on this ground is also of limited application. In experiments with the colour-tests made in the manner described in a former communication, we obtain two classes of results. We may get a mere trace or "flash" of blue, or we may obtain a deep rich blue colour, lasting for several seconds, for half-a-minute, or even for forty-five seconds, and succeeded by the other tints already described. Now those who maintain the value of the colour-tests for

¹ Substance of part of the Croonian Lectures for 1861, delivered at the Royal College of Physicians; from the *Pharmaceutical Journal*.

strychnia do not pretend that a mere flash of colour affords such evidence of the presence of strychnia as could be used with safety in a court of law; but they would probably be found to assert with equal confidence that a deep rich blue colour, developed by the colour-producing tests for strychnia, and continuing for several seconds in a spot previously treated with sulphuric acid without change of colour, and then succeeded by other colours, affords good evidence of the presence of strychnia. Though the blue colour soon passes away, there is ample time afforded for its complete recognition.

In answer to the objection that the succession of colours is difficult to describe or define, it will suffice to state that though it may not be possible by any words that we can use to describe the successive colours developed by the colour-tests, it is not necessary to do so. For the first deep rich blue colour, characterised by the property of want of permanence, is in itself so remarkable as to constitute a most valuable and trustworthy test for strychnia.

The colour-tests for strychnia are certainly open to the objection that the colour-developing substances are themselves coloured. The peroxide of lead is puce coloured, the peroxide of manganese black, the bichromate of potash orange coloured, the ferricyanide of potassium yellow or orange, and the permanganate of potash lilac. The peroxide of lead and the peroxide of manganese also colour sulphuric acid by admixture, and the bichromate of potash, ferricyanide of potassium, and permanganate of potash change the colour of the acid by solution. But it has been shown that the colours thus produced cannot possibly be confounded with the strychnia blue, and consequently form no valid ground of objection.

The fourth of the five objections applicable to chemical tests in general, certainly does not apply with any force to the colour-tests for strychnia; for I can state as the result of experiments with a great variety of substances, vegetable and animal, including all the matters that are likely to remain mixed with strychnia after its extraction from the contents of the stomach, or from the fluids and tissues of the body, and further with many mineral substances, including common salt, arsenious acid, tartar emetic, and corrosive sublimate—all these animal, vegetable, and mineral substances having been added in quantities far exceeding those in which they could possibly exist as impurities in strychnia extracted from the contents of the stomach, or from the fluids and tissues of the body,—that the colour-tests are little, if at all, affected by such admixtures. This observation applies to the permanganate of potash equally with the bichromate of potash.

For practical purposes, the reaction which demonstrates the presence of strychnia may be described as a clear, rich blue colour, developed by the colour-tests in a spot previously treated by strong sulphuric acid without change of colour, the blue colour in question lasting long enough for perfect recognition, and then passing into other colours. In the absence of the blue colour we can affirm the probable absence of strychnia, but a mere flash of colour does not afford a degree of evidence upon which we ought to rely in a medico-legal inquiry.

Assuming the description just given to be correct, I now proceed to inquire whether there are any known substances which give rise to a similar reaction. The answer must be, in a qualified sense, in the affirmative; but it must be understood the reaction is only *similar*, not the same.

Such a substance is to be found in cod-liver oil, which,

when treated with strong sulphuric acid, assumes a purple tint, mixed with streaks of blue, changing after a time to mulberry, and from that to a red-brown. In these changes of colour there is such a general resemblance to the strychnia tints as would justify their being put forward as an objection to the colour-tests, but for the very obvious consideration that with sulphuric acid alone strychnia undergoes no change of colour. The very fact, too, that cod-liver oil is an oil, while strychnia is tested either as an alkaloid or the salt of an alkaloid, as a crystal or as a white powder, or as a dry deposit from a liquid holding it in solution, deprives this objection to the colour-tests for strychnia of all practical value.

Again, aniline is mentioned as a source of fallacy. But aniline is a coloured liquid, which yields with sulphuric acid a dense white precipitate, the sulphate of aniline. Strychnia, on the other hand, is a crystal or white powder, or a dry deposit from a liquid holding it in solution.

But the sulphate of aniline, which is formed by adding the strong sulphuric acid to the liquid aniline, is sold as a white powder, as are some specimens of strychnia. Hence the sulphate of aniline might possibly prove a source of fallacy, inasmuch as it gives no change of colour with sulphuric acid, and yet when treated with the colour-producing substances yields a colour similar to the blue of strychnia. But the sulphate of aniline, in place of a rich, deep blue, passing speedily into mulberry, and at length into bright red, assumes at first a pale green, which deepens by slow degrees, then passes into a beautiful blue, continuing unchanged for a long period, but at length turning to a black. So that the first characteristic colour with strychnia is the second with aniline, and the transient colour with strychnia is persistent with aniline.

Again, there is a red crystalline substance, pyroxanthine, which produces with sulphuric acid alone, without addition of the colour-producing tests, a blue similar to that produced by strychnia. But there is here no real fallacy, because strychnia is not coloured, and does not yield any colour with sulphuric acid alone.

Nor do papaverine and narceine, which are tinged purple by sulphuric acid alone, create any difficulty, or occasion any fallacy. And the same may be said of the whole body of alkaloids and active principles, whether coloured or colourless, which yield colours when treated with sulphuric acid alone. Of those which resemble strychnia in giving no colour with sulphuric acid, it may be stated with equal confidence that not one of them yields with the colour-developing substances the true strychnia colours, or any colours resembling them.

The foregoing are given as examples of the sort of objections that are urged against the colour-tests for strychnia. They belong to the class of objections which no one out of a court of law would bring forward as worthy of serious attention. They are based, not so much on a misapprehension of the facts, as on an illogical comparison of dissimilar phenomena. But there is one objection founded on a misapprehension and quite unintentional misrepresentation, which ought not to be passed over in silence. It is stated by Dr. Taylor, in his work on Poisons, that the alkaloid curarina obtained from the South American poison curara, "resembles strychnia in the action of the colour-tests, brucia in the action of nitric acid, and both in its intense bitterness." These are the words used by Dr. Taylor at p. 786 of the second edition of his work; and on referring to p. 772, he says of the same alkaloid, that "strong nitric acid

produces with it a blood-red colour; sulphuric acid gives with it a rich carmine tint, in which characters it resembles brucia," and, further, that Pelikan found pure curarina to possess the chemical properties of strychnia, so far as the colour-tests are concerned, and with more constant results. Thus, sulphuric acid when conjoined with the action of chromate of potash, ferricyanide of potassium, or peroxide of lead, "produced a beautiful play of colours," and "that the galvanic test acted similarly." Now, on referring to the passage cited from Pelikan, I find that this beautiful play of colours is a translation of the words, "des colorations rouges très belles," and "la coloration rouge," the one expression being applied to the chemical tests, the other to the galvanic test. So that the alkaloid curarina is set up as a fallacy on the strength of its yielding with the colour-tests (sulphuric acid mixed with chromate of potash, ferricyanide of potassium, or peroxide of lead) a brilliant red colour, or colours, instead of the beautiful play of colours, blue, mulberry, and red, which jointly, and not separately, characterise strychnia. If any one colour is to be deemed the strychnia colour *par excellence*, it is the rich deep blue, and not the brilliant red. Let it also be remembered that sulphuric acid gives with curarina, according to Bernard, a rich carmine tint, while strychnia undergoes no change of colour when treated with sulphuric acid. The statement made by Dr. Taylor that in giving a blood-red colour with strong nitric acid and a rich carmine tint with sulphuric acid, curarina resembles brucia, is evidently founded in error. The reaction of brucia with nitric acid is correctly stated, but brucia certainly does not yield a carmine tint with sulphuric acid. It is one of the list of substances grouped together in my tables as characterised by a negative action with sulphuric acid; and Mr. Jenkins, in the table which I sent round in my last lecture, attributes to it a negative reaction with sulphuric acid (see CHEMICAL NEWS, October 6, 1860); and here I may observe that it is one of the obvious advantages of tables such as these that they place before us the common and familiar reactions of the substances which they comprise, in such an orderly and methodical way as greatly to assist the memory, and to guard against such inadvertent statements as this of Dr. Taylor's respecting brucia.*

On referring to the tests for brucia itself, as given at page 801 of Dr. Taylor's work on Poisons, from which I have been quoting, I find it stated that "strong sulphuric acid colours brucia of a rich rose-pink colour." This colour differs widely from the rich carmine (*belle teinte carminée*) of Bernard, said by Dr. Taylor to be characteristic of the same reaction, and I think that I may venture to state of it that it is not the reaction of pure brucia with pure sulphuric acid. Indeed, it is not the reaction of specimens of brucia of ordinary purity with specimens of sulphuric acid of similar purity. To obtain a rich rose pink with brucia, we must use a specimen of sulphuric acid containing an unusual quantity of nitric acid, and I have no doubt that the unintentional use of such an acid gave rise to this misapprehension. I may add, that to specimens of brucia of fair average quality sulphuric acid will impart a very slight tint (rose colour or buff), and a still slighter tint to the solution of the alkaloid in the acid. But a rich rose-pink colour is an evidence of the presence of nitric acid, and is readily developed in the solution of the

alkaloid in sulphuric acid by a short exposure to the vapour of nitric acid.

I could not have accomplished the object I have in view of vindicating the colour-tests for strychnia from unfounded objections, without tracing this particular objection to its true source. It was necessary to show that the reactions of the rare alkaloid curarina, differ essentially from those of strychnia, and of brucia, which is associated with strychnine in more than one of the plants that yield it; and I could not do this without showing that an esteemed medico-legal authority had made a mistake in reference to a reaction, and an oversight in rendering the words of a French author.

I may add, that on comparing the extract of nuxvomica with a specimen of curara poison, for which I am indebted to the kindness of Mr. Morson, and with the brown powder scraped from an arrow tipped with the same poison, and forming one of a collection kindly presented to me by Mr. Stone, of the College of Surgeons, I find no resemblance between the one extract and the other, except in the property of intense bitterness. The woorara poison imparts to strong sulphuric acid a greenish-brown tint, and the nuxvomica a pink colour; while strong nitric acid, which turns the first to a pale, dirty yellow, changes the second to a very distinct orange colour. The addition to the solution in sulphuric acid of bichromate of potash produces less effect on the colour of the curara than takes place with the extract of nuxvomica. If the woorara really contained any alkaloid capable of developing with sulphuric and nitric acids the deep rich colours attributed to it, I think that some approach to those colours might be expected in the extract itself.

I may conclude this part of my subject by expressing my firm conviction that to the colour-tests applied in the manner I have recommended, there is no valid logical objection; and that though a negative result is not conclusive of the absence of strychnia, a positive result (by which I must be understood to mean the development of a rich blue colour on stirring the colour-developing substances into a spot first treated with sulphuric acid without change of colour, the rich blue colour in question passing, after a few seconds, into other colours) affords undeniable proof of its presence.

In my next and last communication I shall endeavour to discriminate the principal alkaloids from each other, and to represent the differences between them by convenient tabular forms.

(To be continued.)

On the Oleaginous Matter formed on Dissolving different kinds of Iron in Dilute Acids, by EMERSON J. REYNOLDS.

PROUST, I believe, was the first chemist who noticed that the hydrogen prepared by dissolving black cast iron in dilute sulphuric acids possessed a most offensive odour, and that on being passed through glass tubes it caused them to assume a greasy appearance, apparently due to the deposition of an oily matter, which he appears to have considered as a combination of hydrogen and iron, the non-production of which body under the circumstances I will demonstrate further on.

Berzelius afterwards noticed the formation of this oleaginous body, and gave it as his opinion that it was a compound of carbon and hydrogen. More recently, Professor Cameron (in 1855) made some experiments on this oil, the results of which he communicated to the

* These tables will be referred to more particularly in my next paper.

Chemical Society of Dublin. He found it to be very volatile, and destitute of nitrogen, and also that certain metallic salts removed the offensive odour produced by its presence.

But, after all, two very important points have been left undetermined, namely, the precise conditions under which this body is formed, and its chemical and physical characters and relations.

Now, it is the first of these propositions that I intend dealing with in the present paper, reserving the second for a future communication. I had contemplated waiting until my investigations were completed before publishing the results; but in consequence of some observations made by M. Chevreul, before the Academy of Sciences of Paris, I thought it better to bring forward what I have determined up to the present time. Chevreul stated that the combination of the iron with the hydrogen seemed difficult to admit, and that this consideration had led him to conjecture that the water might assist in the production of the oily matter. He, moreover, considered that the researches of M. Fremy¹ on cast iron and steel, seemed to throw some light on the subject, by indicating that it is not carbon, as was represented, which yields the oily body. Now, we can clearly gather from this that M. Chevreul points to nitrogen as being, possibly, the principal constituent of the oil, and not carbon.

In order to clear away all doubts as to its origin, it was essentially necessary to answer the three following propositions:—

1. Is the oleaginous body produced during the solution of pure iron in dilute acids?
2. Does iron, free from every other impurity but carbon, yield the oil when treated with acids?
3. Will iron, containing nothing but nitrogen, furnish the oily matter on similar treatment?

It will be seen at a glance, that the careful solution of these propositions would be certain to make us acquainted with the circumstances which influence its production.

The following are the methods which I adopted for answering each question:—

1. My first object was to prepare absolutely pure iron. This I procured by the process generally employed for preparing "*fer réduit*," care being taken to preclude any possible chance of impurity. The peroxide being precipitated from the pure perchloride by ammonia, after being well washed, it was then submitted to a low red heat. Moreover, the hydrogen gas used to decompose the peroxide was evolved from distilled zinc and pure sulphuric acid. The metallic iron so procured, when dissolved in dilute acid, did not yield the slightest trace of the oil. I did not come to this conclusion after one or two experiments alone, but after repeated trials. This overthrows at once the supposition that the iron combines directly with the nascent hydrogen forming the oil, and, indeed, does more, for its non-formation tends to confirm, if such were necessary, the opinion of Dr. Cameron formerly expressed in this Journal, that such a compound as ferruretted hydrogen does not exist.

2. In answering the second question, it was essential to obtain iron containing some carbon in combination; this I prepared as follows:—Carburetted hydrogen in a pure state was passed over the iron of Experiment 1, heated to redness; the action was allowed to go on for half-an-hour. In this way I obtained iron containing carbon—in fact, cast iron. This compound, when dis-

solved in acids, gave the oil in such quantity as to allow of its being identified with the greatest ease. This experiment proves with certainty that carbon is essential to the existence of the oil, though, of course, it does not furnish us with any information as to whether the elements of water enter into its constitution or not. This can only be found by its ultimate analysis.

3. The third point to be considered in connection with this subject is, whether or not nitrogen gives rise to any oil. To determine this, another portion of the iron of Experiment 1 was submitted to the action of dry ammoniacal gas for nearly two hours and a-half, by which means it became highly nitrogenised (as was proved by the abundant evolution of ammonia on heating in an atmosphere of hydrogen). This body, when treated with dilute sulphuric acid, which readily attacks it, does not, when so acted on, give the least trace of oleaginous matter. Of this I have satisfied myself; but, instead, a solution of ammoniacal sulphate is produced.

To sum up, then, my experiments show the following:—

1. Pure iron does not yield the oil.
2. Iron containing carbon does give the oil.
3. Iron containing nitrogen does not furnish the oleaginous matter.

So far for the origin of this curious body: it now remains for me to determine by analysis its composition, &c. On this subject I am actively engaged at present, and hope to turn to some account the experimental results which I have arrived at in this paper, so as to furnish me with a means of preparing this oil in larger quantity than I have heretofore obtained it.

TECHNICAL CHEMISTRY.

On Electro-Chemical Colouring and the Deposition of Peroxide of Iron on Plates of Steel and Iron, by M. BECQUEREL.

PRIESTLY was the first to obtain coloured rings by means of electricity,¹ by receiving strong charges from a battery, with surface of about two square metres, on metal plates, by means of metallic points directed perpendicularly to their surface.

Nobili, in 1827,² afterwards produced coloured rings on platinum, gold, silver, and brass plates, by putting them in communication with one of the two poles of a voltaic pile, plunging them into metallic and non-metallic solutions, and then by directing perpendicularly to their surface a platinum point connected with the other pole. With positive silver, for instance, and solution of sea salt he obtained a series of concentric circles surrounded with varied irises, the tints being slightly dimmed by contact with the air. On heating the plates all the rings took a red tint.

I began to study the electro-chemical colouration of metals in 1843,³ my chief object being, not to produce coloured rings, but to deposit on plates of gold, platinum, copper, and silver, thin and uniform layers of peroxide of lead presenting successively, according to the duration of the operation, which was generally very short, the rich colours of the spectrum. The operation consists in plunging into an alkaline solution of protoxide of lead

¹ *Philosophical Transactions*, vol. lviii.

² *Annales de Physique et de Chimie*, vol. xxxiv., second series.

³ *Comptes-Rendus*, vol. xviii.

the piece to be coloured, put in connection with the positive pole of a voltaic pile charged with nitric acid and composed of many layers of plates, and closing the circle with a platinum wire in communication with the negative pole, and of which but the point, which alone touches the alkaline solution, is continually in motion. In contact with the object to be coloured, the protoxide of lead, which forms the positive electrode, super-oxidises, becomes insoluble in the alkali, and deposits itself on the surface in slight adherent layers, producing the colour of the thin plates. Air and light gradually fade these colours—a disadvantage I have already mentioned, and which may in great measure be avoided by covering the coloured surface with alcohol varnish, which acts but very slightly on the peroxide. With a little practice all the tints desired may be given to a large object with hollows and projections, and each part painted with the appropriate colour. These colours are now made fast by the processes to be described further on.

If the solution of protoxide of lead in potash is replaced by a solution of protoxide of iron in ammonia, and the gold, copper, or platinum plate by one of polished iron, there is deposited on the latter a layer of peroxide of iron with red or brown tints, which deepen more and more according to the thickness of this stratum, which never exceeds a certain limit on account of the imperfect conductivity of the peroxide.

In a paper on the precipitation of metals from their solutions by other more oxidisable metals, I stated that on plunging a copper plate into a solution of double chloride of potassium and platinum, heated to 60°, the platinum is deposited and adheres to the copper, producing a platinization, which is quickly acted on by the air, taking first a slightly brownish tint, which becomes darker and darker.

This alteration is partly due to the presence of protochloride of copper, which is deposited simultaneously with the platinum towards the end of the operation. The protochloride may be removed by washing the platinised copper with water and acetic acid, or by rubbing its surface with cotton and rouge. The alteration is then avoided, or at least does not appear till long afterwards, probably on account of the air traversing the interstices of the platinum, which with copper forms a voltaic pair. The brownish colour of the platinum surface is like that which protochloride of copper ordinarily takes under exposure to air and light.

If we make use of platinised copper directly it is obtained from a solution of double chloride as a positive electrode to decompose water with a pile composed of several elements, it produces, under the influence of the oxygen disengaged from the positive pole, peculiar colouring effects, seeing that the tints pass immediately to blue and deep crimson, and the protochloride of copper is not modified by light. While in contact with platinum the latter metal doubtless contributes to the colouration. No similar result is obtained by operating with platinised plates previously treated with acidulated water or rouge. Furthermore, air has no effect on the colours produced—not an unimportant fact, as it will make it possible to obtain fast colours also with peroxide of lead.

Owing to the strata of oxide, the result is the same if heat is gradually applied to non-preserved platinised pieces, but the colours are less brilliant.

If a copper plate with a layer of peroxide of lead giving one of the beautiful colours of the spectrum is employed as a positive electrode to decompose the water,

in a few moments it will be found that the coloration is preserved—a result similar to that obtained with platinised copper. By continuing the electro-chemical action for a quarter or half-an-hour, according to the force of the pile, the blue-violet tints fade, turning to green and yellow, as peroxide of lead. The basis of the coloration undergoes no change at the positive pole. It is thought that the acid secondary products formed at the positive pole react on the peroxide and decompose it.

The coloured plates thus preserved seem to be in the same condition as iron when it has been plunged in nitric acid, or when it has been used as a positive electrode to decompose this same acid. It is then in an abnormal state, being unattackable by nitric acid.

When a very slight layer of platinum is electro-chemically deposited on a gold or platinum plate by means of a solution of double chloride of potassium and platinum containing no copper, this layer undergoes no change either by the action of the air or when the plate is employed as a positive electrode to decompose water; but it is otherwise when the solution contains copper. The colouring effects before described are then produced, when the proportion of copper is small and the coloration of the platinum is not destroyed by weak nitric acid—an important advantage practically. In this memoir we have indicated a great improvement in the process of coloration, for by its means more uniform and adherent layers of metals are deposited.

Magnificent colouring effects are produced by a solution of double chloride of potassium and platinum in hyposulphite of soda.

Lastly, deposits of peroxide of iron on iron and steel, which are already almost unalterable by air, will become entirely so when the pieces have been employed as positive electrodes to decompose water.—*Comptes-Rendus*.

PHARMACY, TOXICOLOGY, &c.

Plasmata or Glycerine Ointments.

THE use of a simple plasma or glycerine ointment in eczema and other skin diseases has been common for some years, both in Germany and England. Of late, however, Graefe, of Berlin, has employed it as a vehicle for the application of various active remedies in diseases of the eye.

Simple plasma is made by heating one part of starch with seven parts of glycerine. The heat of a water-bath is not quite sufficient to effect the solution of the starch; and great care must be taken in regulating the heat and continually stirring the mixture to prevent burning. When atropia or belladonna are to be combined with this simple plasma, it will be very important to avoid the burning, which, besides giving a disagreeable appearance and smell, will in these cases seriously affect the remedial value of the compound.

The advantages which this compound possesses over lard, or mixtures of oil and wax, as a vehicle for active remedies, are, that it is soluble in water, retains its consistence at all ordinary temperatures, and, lastly, does not become rancid. It does, however, after a time (usually several months), become mouldy on the surface, but this can be easily removed, leaving the remainder quite good.

With this simple glycerine ointment various substances are now combined, such as atropia, extract of belladonna, extract of opium, sulphate of copper, acetate

* *Comptes-Rendus*, vol. xlvii.

of lead, the ammonio-chloride, nitric oxide, and sub-nitrate of mercury and nitrate of silver. The last is said to be used in Germany, but appears to us a most ineligible compound, for the nitrate commences to decompose the moment it is brought in contact with the starch, and in a very short time is completely reduced.

The plan adopted in the preparation of these ointments may be varied, according as the active agent to be introduced is soluble in glycerine or not. In the former case, as with the extracts before mentioned, atropia and sulphate of copper, they should first be dissolved in the glycerine, and the solutions of the extracts, if necessary, strained; the starch should then be mixed with the solution in a mortar, and the mixture transferred to an evaporating dish to be heated. If the active agents are insoluble in glycerine (as the mercurial salts), they should first be thoroughly mixed with the starch before the glycerine is added. In each case it is advisable to stir the mixture industriously while the heat is applied, as well to ensure the proper distribution of the ingredients as to prevent the burning.

We now proceed to give the formulæ for the compounds which are in use and about to be introduced into the Pharmacopœia of the Royal London Ophthalmic Hospital. It must be premised that the solubility of the menstruum permits the use of a smaller quantity of the active ingredient, and it will be seen that when there is a corresponding ointment in the London Pharmacopœia, the plasma has half the amount of the active ingredient.

Plasma with Sulphate of Copper.

℞ Cupri sulphatis . . .	gr. xxiv.
Pulveris amyli . . .	3jss.
Glycerinæ . . .	3xss.

First dissolve the sulphate of copper in the glycerine, then mix the starch, and heat until the plasma acquires a proper consistence. The sulphate of copper being soluble in the glycerine, this forms a very elegant preparation, of a delicate, transparent, greenish-blue colour.

Plasma with Extract of Belladonna.

℞ Extracti belladonnæ . .	gr. xlv.
Pulveris amyli . . .	3jss.
Glycerinæ . . .	3xss.

First dissolve the extract of belladonna in the glycerine, and, if necessary, strain; then mix the starch with the solution and heat carefully, stirring continually until the plasma acquires a proper consistence.

Plasma with Ammonio-chloride of Mercury.

℞ Hydrargyri ammonio-chloridi .	3ss.
Pulveris amyli . . .	3jss.
Glycerinæ . . .	3xss.

Plasma with Nitric Oxide of Mercury.

℞ Hydrargyri nitrico-oxidi .	gr. xlv.
Pulveris amyli . . .	3jss.
Glycerinæ . . .	3xss.

Plasma with Subnitrate of Mercury.

℞ Hydrargyri subnitratis .	gr. xl.
Pulveris amyli . . .	3jss.
Glycerinæ . . .	3xss.

These three preparations may all be made in the same way. The mercurial salt should first be intimately mixed with the starch and then the glycerine added. It is, of course, important in each case to stir well while the heat is applied. The plasma with the subnitrate is intended to be used in place of the unguentum hydrargyri nitratis,—a preparation to which it does not, however, fully correspond. But there are objections to boiling an acid solution of mercury with glycerine, and if the cold

acid solution be mixed with the plasma it soon becomes almost liquid. The liquid preparation, however, might be useful under some circumstances. The preparation is intended to represent an ointment half the strength of the unguentum hydrargyri nitratis of the London Pharmacopœia.

Plasmata with extract of opium and atropia and acetate of lead may also be easily made. Extract of opium dissolves in glycerine, and this plasma may be prepared in the same way as that with extract of belladonna. When atropia is used great care must be taken in heating the mixture, as the atropia is destroyed at a temperature a little above that of boiling water. Two grains of atropia to one drachm of the plasma is a convenient strength for dilating the pupil of the eye.

PHYSICAL SCIENCE.

On the Nature of the Spark of Ruhmkorff's Induction Apparatus, by M. ADOLPHE PERROT.

1. THE induction spark, which explodes between the extremities of the induction wire in Ruhmkorff's apparatus, when the inductor current is interrupted, possesses at the same time the property of tension, more especially characteristic of the static state, and the properties of quantity characterising the dynamic state.

2. This spark may be divided into two parts, one possessing only the qualities of tension, the other those distinguishing the dynamic state.

PROCEEDINGS OF SOCIETIES.

THE SOUTH KENSINGTON MUSEUM.

Monday, January 7, 1861.

On the Importance of the Study of Chemistry, by A. W. HOFMANN, LL.D., F.R.S.

IN compliance with an invitation from the Committee of Council on Education, I will endeavour to bring under your notice some considerations on the Study of Chemistry as part in a well arranged system of mental cultivation. In an attempt of this kind, owing to the endless variety of relations which chemistry bears to other branches of knowledge, so many starting points present themselves, that it seems important to define at the very outset the aspects under which I propose to submit the subject to your attention. I may, therefore, state at once that I shall examine the question more especially in two directions, aiming, in this first Lecture, at giving you a survey of the conditions which render the study of chemistry invaluable as advancing the material well-being and the intellectual progress of mankind, and pointing out in a second Lecture, the path recognised by experience as the shortest and safest towards the perfect mastery of chemistry as a science; adding at the same time, some remarks on the chemical instruction in schools, where chemistry is taught as a branch of general education, and as a means of mental training.

The importance of the study of the natural sciences, and particularly of chemistry, becomes at once obvious when we compare our modern civilization with that of antiquity. Losing sight of the revolution brought about in the human mind by the reception of new religious views, as not immediately connected with the subject of this discourse, it

¹ Abstract of a paper in the *Annales de Chimie et de Physique*, sect. 3, vol. lxi. pp. 200—223.

cannot be denied that all the other steps of progress which modern times have made, are exclusively derived from the ardent cultivation of the study of nature.

In poetry and sculpture the ancients are still unsurpassed. What epic poem, as to originality, vigour, and freshness, can be compared to those of Homer? We admire the genius of a Shakespeare, the searching eye with which he traces human nature to her innermost recesses; we are carried away by his life-warm creations. Whether he reveal the tenderest emotions of the human breast, or roll before our view the stormy waves of passion, we unhesitatingly accord to him the palm as the first dramatic poet of modern times. Let those, however, who have read the Greek tragedians say, whether Sophocles has been surpassed by Shakespeare!—Modern sculpture ever turns to the antique as to a model of unattained perfection. In all times, from all countries, the sculptor has made his pilgrimage to Rome and Greece to study in the school of the ancients.

He who has seen the frescoes on the walls of Pompeii will bear witness to the high attainments of the painters of those ages, and, granting a great development to the art of painting in modern times, it would be difficult to say how far this is owing to our different mode of viewing the world, which has altogether changed the scope of artistic aspiration, or to the technical improvements, more especially in the colours, which are at present at the disposal of the painter. It is next to impossible to form a clear notion of the music of the ancients; but if we consider the simplicity of the instruments at their command, there can be no doubt that the advance, which modern music has made, is mainly referable to our perfected construction of their instruments, and to the invention of new instruments, for which again we are indebted to an active study of the laws of nature.

Our writers of history, too, in what do they surpass their predecessors except in the endless abundance of material which century after century has heaped up in addition to what they possessed? The writings of the ancient historians are still the first which we place in the hands of our youth, and experience has proved what an inexhaustible source of mental and moral culture successive generations have found in these works. No nation of modern times has produced more brilliant orators than England; as none possesses freer institutions, the native soil of eloquence. But have modern orators outstripped the Greek and Romans (except, perhaps, in the formidable length of their speeches)? To him who would ascertain what progress the schools of mental philosophy in later times have made, compared with those of antiquity, I recommend a plunge into the works with which a certain school deluged the literature of Germany at the commencement of this century. Again, has not modern jurisprudence its very root in the Roman law? Is not the Roman law taught at this very day in all the continental universities? and is not the civil law of the Romans still in force in many states at the present time? I may be reminded of the enormous strides which the mathematical sciences have made in modern times, but we still learn from Euclid the rudiments of geometry: and are we quite sure that the methods, which, like so much new apparatus, has been supplied to mathematical operations, would have unfolded themselves, had it not been for the wonderful development of the natural sciences, more especially of physics, which continually offered to mathematical treatment new material to be mastered, and thus in a measure involved the creation of these very methods?

I might easily pursue this parallel still farther, but I have already said enough for my purpose.¹ Modern

civilization most undoubtedly has its footing in the zealous investigation which the present age has devoted to the forces of nature, and in the wonderful results to which this investigation has led, and, day by day, is leading. The study of the forces of nature has subjected them to our will. Knowledge is power; under no conditions is this axiom truer than when applied to the knowledge of natural phenomena. Time and trouble spent on the study of nature is amply repaid, for in every well examined physical force, man educates for himself an obedient servant, ready at all times to fulfil his behests.

What giant strides in all directions have been made in consequence of the development of the various branches of physical knowledge? The power of steam has gradually become subservient to such a variety of uses that we can scarcely imagine our existence without it; and yet when we see our steamships cleaving the ocean from hemisphere to hemisphere, or the locomotive engine rushing with the speed of the storm over the country, how rarely does it occur to us that we are indebted for this rich inheritance to the patient study of the laws of heat? Were I to pursue, into its various directions, the influence which the substitution of steam power for the uncertain forces of water and wind, or for animal force, has exerted on the several arts and manufactures, I should exceed the limits of this sketch; but I am tempted to glance for a moment at the wonderful change which the introduction of steam has produced in the civilization of nations. We are still far distant from the reign of uninterrupted peace; the clang of arms no sooner ceases in one country, than the flames of war are seen raging in another, but how different in form and fashion are our wars from those of antiquity! We still wage war, but no longer for the purpose of enslaving entire nations. We need no slaves, steam engines are our slaves, our helots. The constructions of our architects, and of our engineers, are not less grand than the pyramids of ancient Egypt, whilst they are immeasurably more useful; but no longer are the inhabitants of whole provinces made to groan for years like beasts of burden, no longer is the towering pile cemented by the sweat of an enslaved people.

A harvest of results, not less unexpected, has rewarded the inquiries in electricity, a science of which antiquity had not even an anticipation. A century has not passed since Franklin made his experiments with the electric kite; a shorter time has elapsed since Galvani saw the frog's leg quiver on the balcony at Bologna, and scarcely have the inquiries been completed which place in its true light the connexion between the experiments of both observers; but what incalculable advantage has not the human race already reaped from these observations! Everyone knows that Franklin was led by the prosecution of his experiments to the invention of the lightning-conductor, and that the elaboration of Galvani's observations gave rise to the construction, in the hands of Volta, of his battery, that grand lever of our own times. A faithful handmaid, the voltaic battery multiplies for us, in durable metal, the noblest productions of artistic genius, formerly accessible only to the chosen few, and this with an accuracy of which no other mode is capable. Not satisfied with giving an exact copy of the form, it clothes the copper with a layer of silver or gold, almost imponderable, yet sufficiently close and uniform to protect the delicate surface against the tooth of time. Beaming from the lofty pharos, the electric ray warns the seaman from the treacherous rock, and guides him safely into port. As a winged messenger, lastly, annihilating time and space, the electric current bears our thoughts with the rapidity of their conception over land and under sea. Great as these acquisitions are, the list of benefits which our generation is destined to reap from the study of electricity is not yet concluded. It was by the help of the voltaic battery that Davy, at the commencement of this century, was enabled to decompose the alkalis into

¹ The subject has been very fully treated by Professor Pettenkofer in one of his popular lectures. In the same lecture the author lucidly explains the causes which, in antiquity, prevented the free development of the study of nature.

their elements. The isolation of the alkali-metals has at all times been considered one of the finest achievements of chemistry. During the half century that has since elapsed, it has afforded incalculable aid to the progress of science; but it was reserved for our time to hail on the market-place of life this glorious discovery of Davy. By the help of one of the metals discovered by Davy,—by the help of sodium,—chemists had succeeded in separating from common clay a metal, equally distinguished for its peculiar white lustre, its lightness, and its resistance to the atmosphere. The industrial production of aluminium, which is of unlimited occurrence in Nature, had been impeded hitherto by the high price of the sodium necessary in its extraction. By the unremitting efforts, however, of H. Ste. Claire Deville, the preparation of sodium has lately become so simplified and so cheapened, that the manufacture of aluminium on a large scale has been actively carried on for some time; and thus we owe to the combined inquiries of chemistry and physics, an industry, the future of which it would be difficult at this moment to calculate.

Scarcely less rich and interesting are the acquisitions which modern times have derived from the assiduous inquiries into the nature of light. To the comprehension of its laws, we are indebted for the perfection of the instruments, which, embracing as it were the infinite in both directions, have gathered the vastness of the heavens within the sphere of our perception, and expanded to our view the living world in the water drop. The phenomena of polarization, but a few years ago the exclusive property of abstract science, have taken their place among the adaptations of optics to practical life. Aided by the polarizing prism, the navigator may search the seas for the shoals threatening his destruction, and the fisherman follow the movements of his prey through depths impenetrable to his unaided eye. In the hands of a Biot, a ray of polarized light became, to the sugar manufacturer, an index of the amount of saccharine matter contained in his liquors; whilst directed by the genius of a Wheatstone, we have seen it performing the work of a chronometer. (Playfair.²)

The method of fixing the picture of the camera obscura, that marvel in the history of science, placed, as it were, on the boundary line between optics and chemistry, directs our consideration more especially to the fruits reaped from chemical inquiry.³ The study of the solar ray led the way to the contrivance of an instrument, which, imitating the structure of the human eye, presents within a narrow compass a faithful copy of the grandest scenes and of the most fragmentary miniatures of nature and art. To this picture, the fugitive offspring of a passing ray, chemical science has given permanent life. But before this discovery, which is one of the most graceful achievements of our own times, could be accomplished, what thought, what toil was necessary; what a series of researches were required, perfectly unconnected with the final result, which nobody could have anticipated! The ley of the soap-boiler had to give up its iodine: the properties of this new element, and its action on various other substances had to be carefully studied; the investigation of sulphur and its oxides had to teach us the existence and the properties of hyposulphurous acid; gun-cotton, lastly, of ephemeral celebrity whilst threatening the world with destruction, had to be tamed down to the permanent usefulness which it possesses in the form of collodion.

Photography is not the only fruit which has arisen from the union of optics and chemistry. The last few months have given evidence of the treasures which are still to be raised on the boundary domains of the two sciences.

It is well known that the spectrum of a flame, of a gas-flame, for instance, in which certain substances are volatilized, exhibits peculiar bright lines, the colour and position of which varies according to the nature of the substance. These phenomena, investigated by several observers, and more especially by Plücker, have lately been further pursued by Kirchhoff and Bunsen. Their experiments have led to truly astonishing results. Not only have these philosophers been enabled to endow science with perfectly new methods of research, in comparison with which the ordinary modes of analysis are coarse and clumsy; but the delicacy of their process has permitted them to recognise the existence of new elementary substances, which, like satellites, accompany the commoner elements. Within the last few weeks they have announced the discovery of a new metal, very similar to potassium, for which they have proposed the name of *cæsium*, from the Latin word *cæsius*, expressing the peculiar greyish blue colour of the spectrum line, the observation of which gave rise to this remarkable discovery.

I have in the first place directed your attention to the achievements which Chemistry has accomplished in conjunction with her older sister, Physics. Many of the phenomena which constitute the domain of chemistry, have been known for centuries; but it is only in modern times that this knowledge has been raised to the rank of an independent science. Little more than half a century has elapsed since chemical knowledge became chemical science, yet how manifold are the services which this new science has rendered in so short a period! It was in the latter half of the last century that the combined activity of some of the rarest minds working in various countries began to spread light over this field of knowledge. The genius and laborious researches of a Black, a Priestley, a Watt, a Cavendish in this country, of a Lavoisier in France, and a Scheele in Sweden laid the foundations of the grand edifice which has since been raised by the united labours of scientific chemists throughout the world; they were the workers out of the principles of that enlightened method of interrogating Nature, the introduction of which into the arts and manufactures has effected more in the brief space of fifty years, than the unmethodical experiments of many previous centuries had achieved. The "transmutation of metals," and the "*elixir vita*," which had eluded the ardour and the perseverance of the alchemist, became the legacy of the scientific chemist, who searched for the philosopher's stone, not in sowing the metals, not in the fragrance of flowers, or in the brilliancy of the morning dew, but in the faithful study of Nature's phenomena, and in the investigation of her laws throughout creation. Modern chemistry has not attempted to convert lead into gold, but what immense sources of individual and national wealth have been opened since the adoption of its methods has infused new life into every branch of industry! On comparing the acquirements of the present age, our comforts, our sanitary regulations, our means of communication, &c., with the state of things in the last century, it may with truth be said that human life has actually gained in duration, while its enjoyments have been increased a thousand fold. It would be both interesting and useful, did this brief sketch admit of it, to notice the effects of chemical knowledge on the various branches of industry in every department of life. It would be found, that not only every art and every trade, but that every individual, had profited by the labours of the chemist.

In taking a retrospect of the rapid progress which some of the arts and manufactures, depending upon chemistry, have made in modern times, we are at a loss to know

² The Study of Abstract Science Essential to the Progress of Industry. "Records of the School of Mines," Part I. 1852.

³ Some years ago I delivered a lecture on the Importance of the Study of Experimental Science, in a national point of view, at one of the evening meetings of the Royal College of Chemistry. Several of the illustrations given in the text are quoted from this lecture, which was never published, although a small number of copies were circulated among the Members of the College.

where to begin our survey, every branch of industry could furnish the most brilliant illustrations.

Were I to trace with you the history of sulphuric acid, from the moment when the Erfurt monastery first witnessed oil of vitriol passing over, drop by drop, from the alembic of Basilus Valentinus, up to the present time, when hundreds of thousands of tons are sent forth from the colossal lead-chambers of Great Britain alone; were I to enlarge on the influence which chemistry, by raising the production of sulphuric acid to its present degree of perfection, has exerted on the development of chemical manufactures; were I to describe the action of sulphuric acid in the preparation of the other acids, of nitric, hydrochloric, of acetic acid; its application in the manufacture of phosphorus, its employment in the improved process of candle-making, in the isolation of stearin from crude tallow, its use by the dyer for preparing his colours, by the skin-dresser for opening the pores of the skin previous to the operation of tanning; by the metallurgist in the new process of refining silver; by the agriculturist in the preparation of most efficient manures,—I should have to unfold a picture for which it would be difficult to find the appropriate frame. Nor could I omit to show you Leblanc struggling with prejudice for the adoption of his great discovery: the transformation by the agency of sulphuric acid of sea salt into carbonate of soda; or to lead you into the busy factories of Lancashire, which now, after the lapse of less than half a century, provide not only this country, but half the world, with soda. Nor would the picture be complete without the glassworks and the soap manufactories in the distance, the operations of which have been forced into unprecedented activity by the production of soda, without the bleaching yards, which owe their very existence to Leblanc's great discovery!

It would be equally instructive to trace, in brief outlines, the history of coal gas, the manufacture of which has become, during the last thirty years, of truly national importance.

The evolution in different localities of inflammable gases from the ground has been noticed from time immemorial, and the connexion of these gases with deposits of coal had been recognised as early as the middle of the seventeenth century.⁴ Years, however, elapsed before correct views of the nature of these gases were established by experiment. In 1739, coal was for the first time subjected to distillation by Dr. Clayton, Dean of Kildare, who thus succeeded in imitating artificially the formation of native gas. From this moment the subject was never lost sight of, but it was not till the end of the last century that the intellectual impulse of that memorable period overcame the difficulties opposed to the practical application of this new source of light. These obstacles we know have been at last entirely removed, gas light is now universal. Our streets, our public buildings, our private dwellings, are brilliant with its radiance. In our daily enjoyments of its benefits, we have almost ceased to be conscious of the comfort and even personal security, which we owe to this, as yet, the best, cheapest, and safest of lights.

But, to the attainment of this end, how many were the scientific problems to be solved, how often had the gas-maker to seek the assistance of the scientific chemist, and to avail himself of the results of his researches, instituted originally perhaps for very different purposes! What a difference between the gas with which Mr. Murdoch lighted up the Soho Foundry in Birmingham, and that now circulating in the arteries of our nightless towns!

The gas produced by the distillation of coal is not an uniform substance. Together with the principal illuminating constituents, light carbonated hydrogen and olefant gas, many other gases are evolved during the distillation, some of which, *e.g.* hydrogen, tend rather to

diminish the illuminating qualities of the gas, whilst others, as ammonia and sulphuretted hydrogen are injurious to health. This formed a serious obstacle to the adoption of coal-gas as a domestic light. By the aid of chemistry, the composition of coal-gas was ascertained, and the nature of its constituents, useful and deleterious, determined. Founded on the knowledge thus obtained, means were devised for the separation of the latter; the temperature was indicated, at which the purest gas comes over during the process of distillation, whilst for the improvement of gas less rich in illuminating constituents, the beautiful and economical process of naphthalisation was suggested. And, finally, simple and elegant burners were contrived for the safe and economical combustion of the product.

The extent to which the use of gas has affected the arts and manufactures in this country can only be conceived by those who are aware of its innumerable applications in the double capacity of giving heat and light. The benefits afforded by gas to our experimental chemists cannot be overrated, more especially in England, where the price of spirits of wine was at one time so exorbitant. But for the use of gas in the laboratory, the progress of chemistry in this country must have been greatly retarded.

In speaking of the general influence of the manufacture of coal gas, it is impossible to leave unnoticed the number of hands daily engaged in raising whole strata of coal, and in loading and navigating the fleets employed in conveying it, not only to the different parts of this kingdom, but to foreign countries, which consume a much larger quantity of English coal for the production of gas than is generally known. The extension of the gas enterprise produced a sensible effect on the iron works by the vast number of retorts, the stupendous gas-holders, and the endless pipes, required for generating, storing, and conveying the gas. Several other branches of trade were also forced into increased activity, and even new trades sprang up in consequence of the extended use of gas. The substances produced in the purification of gas naturally attracted the attention of the gas manufacturer; and chemistry soon pointed out valuable purposes to which they might be applied. The oily matter, which is separated as a secondary product in the distillation of coal, has been the subject of various chemical researches, amongst which must be singled out the elaborate investigations of Charles Mansfield, a young chemist of extraordinary promise, whom a cruel fate tore away to early from science and his friends. His researches showed the more volatile portions of this oil to consist chiefly of benzol, an interesting compound discovered some years previously by Faraday. The history of benzol alone and its uses would fill a little volume. Capable of undergoing in the hands of the chemist an endless number of Proteus-like transformations, this substance has not only assisted the progress of science itself, but given rise to new and important branches of industry. Let me remind you that benzol is the most convenient solvent for caoutchouc; that, as an agent for removing oil and grease, it has become an ordinary household article; that, in perfumery and confectionery, we use it as a substitute for the essential oil of bitter almonds; let me remind you, lastly, that, converted by a succession of chemical processes into aniline, it has given rise to the production of those beautiful mauves, purples, and crimsons in which the lovelier portion of mankind is now indulging to the exclusion of almost every other colour. Nor have the other products of the distillation of coal, which accompany the benzol, proved less useful; the liquid distilling at a very high temperature was found to

⁴ Mr. Shirlky's experiments on the burning well of Wigan, in the *Transactions of the Royal Society for 1659*.

⁵ Charles Blachford Mansfield died (February, 1855) a victim of his scientific zeal, in consequence of an accident which happened to him whilst he was engaged in experimenting with benzol. The memory of this young man, in whom intellectual powers of the highest order were wonderfully blended with the rarest gifts of the heart, will be cherished by all those who had the good fortune of meeting him during his short but useful career.—A. W. H.

be an efficient preservative of timber, and the pitchy residue formed the chief ingredient of an excellent substitute for the flag-stones of our pavement, while the ammoniacal liquors were found useful in improving the fertility of land. Thus, after the lapse of countless ages, was the nitrogen of petrified fern forests resuscitated in the ammoniacal liquors of the gas-works, to vegetate once more, and increase the produce of our corn-fields.

In giving you a brief outline of the influence which the study of chemistry, by the development of the manufacture of sulphuric acid and of coal gas, has exerted on the progress of civilization of the present time, I have selected as illustrations two branches of industry, which are essentially of modern growth. Let us now glance at the benefits conferred by the development of chemistry on some of the arts, which formed the legitimate pride of antiquity.

Take architecture as an example. In Rome this art had reached the highest degree of perfection. The temples, the theatres, the aqueducts of the Roman architects, half ruined as they have been handed down to us, are justly admired as glorious monuments of their taste, of the vastness of their conception—of their constructive powers. It is generally believed that the Romans have been the inventors of the ordinary mortars, some of their earlier buildings being constructed without the intervention of mortar. They certainly discovered the hydraulic mortars, which they subsequently used in all their marine buildings. The material originally used by the Romans in the preparation of hydraulic mortars, was the volcanic rock which abounds in the neighbourhood of Vesuvius, more especially near the town of Puteoli, the Puzzuoli of modern times. Ground to a fine powder and mixed with slacked lime, the dust of Puteoli, *pulvis Puteolanus*, has the remarkable property of hardening under water. When the Romans penetrated into Germany, they found the same material in the valley of the Rhine and in the volcanic districts of the Eifel. For nearly 2000 years the rocks of Puzzuoli and the trass-quarries of the Rhine were the only sources from which this valuable article could be derived. It was reserved to the science of our own age to unravel the mystery of hydraulic mortars. The attention of scientific inquirers was forcibly drawn towards this subject, when, at the close of the last century, Parker and Wyatt made the important discovery that the calcareous nodules, which are found in the clay of the London basin may be converted by simple burning into an excellent hydraulic mortar, which had, moreover, the advantage of requiring no addition of lime. Patented in 1796, this discovery led to an important branch of industry—to the manufacture of "Roman cement." The question of hydraulic mortars had entered upon a new phase by becoming the subject of scientific investigation. Geology and chemistry were appealed to, and it was not long before a satisfactory answer was obtained. Several observers have participated in this examination, but it was not until a prize, proposed by the Society of Harlem, elicited in 1828 the classical inquiry of Fuchs, and based the production of artificial hydraulic cements upon a scientific foundation. It would transgress the limits of this fugitive sketch were I to trace, step by step, the gradual development of the chemical theory of hydraulic cements; the question has been very ably discussed by Professor Pettenkofer,¹ who in our own days has materially assisted in the final elucidation of this subject. Suffice it to say that the conditions involved in the solidification of water-mortars are now known, and that every country possesses the materials for the artificial production of what was once the monopoly of the Bay of Naples and the valley of the Rhine.

(To be continued.)

NOTICES OF PATENTS.

Manufacture of Alloys of Titanium and Iron. Improvements in the Manufacture of the same Alloys. ROBERT MUSHET.

THESE specifications refer to modes of treatment for the reduction of an alloy of iron and titanium from the magnetic iron-sand, which occurs so abundantly in the neighbourhood of Taranaki, New Zealand. Mr. Mushet proposes to overcome the difficulties which stand in the way of successfully reducing this ore in the ordinary blast furnace by incorporating the titaniferous iron-sand either with pitch, tar, resin, or bitumen, previously to its introduction with the fuel (coke or charcoal) into the blast furnace or cupola. Mr. Mushet claims, also, the production of an alloy of titanium and iron from the compound ores of titanium, termed "ilmenites" by mineralogists. The advantages anticipated in the above mode of treatment will consist, firstly, in the more appropriate state of aggregation of the powdery iron ore prior to its introduction into the furnace, thus preventing the choking of the air-passages in the fire, which has always been the consequence of attempting to employ the iron-sand in its natural condition; secondly, the intimate incorporation of the finely divided ore with carbonaceous materials would be calculated to facilitate the reduction of the iron, and with it some of the titanium also present in the compound ore.

Improvements in the Manufacture of "Iron and Steel" and of "Cast Steel." ROBERT MUSHET.

THESE patents have reference to the alloying of titanium-iron with either cast steel, puddled steel, or with sundry products of the iron refinery furnace. The intention of the patentee is to produce from iron in various degrees of carbonisation superior descriptions of steel and other metals having valuable properties.

Improvements in the Construction of Furnaces for Melting Glass. W. PILKINGTON.

THIS invention consists in the adaptation of a steam boiler to the ordinary form of glass furnace. An arrangement of iron pipes is made to deliver jets of steam into the caves beneath the furnaces, where they are caused to impinge upon the lower surfaces of the grate-bars, with the twofold object of keeping them cool, and of supplying steam mingled with air to sustain the combustion of the fuel.

Improvements in the Manufacture of Paper. T. RICHARDSON, Newcastle-on-Tyne.

MR. RICHARDSON proposes to mix with the ordinary pulp for paper-making, certain phosphates, employed either alone, or conjointly with sulphites. The phosphates of lime and magnesia are particularly specified. This admixture is intended to supply mineral matter to the paper, and to be used as a substitute for gypsum and kaolin; the excessive proportion of which in some descriptions of paper has recently been pointed out in the *CHEMICAL NEWS*.² Less gritty than kaolin, the phosphate of lime would be found very similar in character to the sulphate (gypsum), and when employed in moderate amount would probably be considered a legitimate mineral ingredient in paper-making.

Improvements in Treating Bye-Products arising in the Manufacture of Soda and Potash for the Attainment of Anti-chlores, and other useful Products. J. TOWNSEND and J. WALKER, Glasgow.

THE patentees expose the waste oxy-sulphide of calcium (obtained in soda-works) to the action of atmospheric air,

¹ Popular Lecture.

² *CHEMICAL NEWS*, Vol. III. p. 329.

whereby they obtain hyposulphite and sulphite of lime. The peculiar manner of effecting this conversion constitutes their first claim. The sulphite and hyposulphite of lime resulting are used in combination with either of the sulphates of soda, potash, ammonia, or magnesia, for producing paper makers' antichlore. The insoluble portion of the oxidised waste is treated with caustic or carbonate of soda or potash to furnish sulphite of soda or potash. And, finally, the patentees claim the obtaining of sulphur and oxides of manganese; also a bye-product in the alkali manufacture.

Manufacture of Gas. W. CLARK. (A Communication.
Not proceeded with.)

IN this invention it is proposed to introduce hydrogen gas into the retorts used for the distillation of coal, and by this means so to dilute the illuminating gas as to prevent in a great measure its decomposition by contact with the red-hot inner surfaces of the retort. The hydrogen is to be stored in a separate gas-holder and passes thence through an iron pipe set across the furnace in a position where it may receive the waste heat. The hydrogen thus becomes moderately heated before it enters the gas-retort, and there combines with the highly illuminating gaseous products disengaged during the distillation of the coal.

CORRESPONDENCE.

The Sale of Poisons.

To the Editor of the CHEMICAL NEWS.

SIR,—It afforded me great pleasure to read the letter of your correspondent, W. Bennington, on the sale of poisons. It is very deplorable that a subject of so much importance as this should have been dropped, and so easily forgotten. I hope now that it is again agitated, it will not be deserted without some practical benefit having been derived from it. I quite agree with him that all future chemists should pass an examination testing their ability. In answer to the objection raised, that this would be a work of time, and that it would be no guarantee that those who are at present in business are competent to fulfil the duties required of them by the public. I reply, it need not be a work of so long a time as many suppose. Suppose that a Society were formed for the examination of chemists as to their competency to vend drugs and poisons, and a Bill passed with the following clauses:—

1st. That no person should commence the business of chemist and druggist who had not passed the above Society and obtained a certificate of his competency.

2nd. That no young man should be accepted as assistant who had not passed and obtained a certificate.

3rd. That all apprentices should pass, prior to the expiration of their term of apprenticeship.

4th. That all chemists under a certain age (suppose 35 years) should pass an examination within one year after the time of the Bill passing.

5th. That if any one should sell drugs, or call himself a chemist or druggist, without having obtained a certificate, he should pay a certain fine.

6th. That each candidate should be examined in Latin, as far as requisite for a correct translation of prescriptions, &c., and in the nature and medicinal properties and dose of each medicine, &c., &c.

7th. That each candidate should pay a certain sum for each examination.

8th. That each candidate should, if unsuccessful the first time, offer himself three other times, and that three months should expire between each examination.

9th. That each member should pay a small subscription annually to defray the expenses of the Society.

Of course, Sir, other clauses would be requisite, which I leave for some of your readers more competent than myself to add; no doubt it will be a hard struggle, and much must be done before this can be accomplished, but as unity makes strength, let us unite and give a strong pull, and we shall at last come off victorious. I doubt not that such a Society, protected and sanctioned by Government, would be the only means for lessening the many deplorable cases of poisoning which daily present themselves to our view. Many would object to such a Society; but I think no educated chemist would, only those who have never spent one day in studying the properties of those drugs which they daily sell. I am not merely surmising such to be the case. I know many that have walked out of a factory into a "Chemist's" shop, and have taken the title of "Dispensing Chemists," whilst they know nothing about the doses and properties of those drugs which they daily sell. I am personally acquainted with many cases of poisoning, resulting from the fact that such ignorant persons are allowed to sell such dangerous medicines, without knowing or giving the proper caution; but have there not been sufficient already to act as a strong and powerful stimulant to induce us to do something, and to cry to each slumberer, Rise, come to help us? I hope that others of your readers will take the subject up, and that soon something may be done to lessen this great evil. I do not wish, Sir, that anyone should suppose that I mean the beforenamed clauses to be arbitrary, far from it. I only offer them as rough timber which requires to be planed and formed into a noble edifice by some clever builders, into which we may run for protection. Having no apology to make, save the importance of the subject,—I am, &c.

R. J. RUTTER.

Uttoxeter.

[Our correspondent seems to be unaware that the Pharmaceutical Society has been labouring for years to do nearly all he suggests, and has so far obtained an Act of Parliament, which gives an exclusive right to the title "Pharmaceutical Chemist" to gentlemen passing the examination of the Society. Further power than this it is not likely, nor perhaps advisable, that the Society should obtain; but we may add that a movement is on foot which will place the question before Pharmacutists and the Medical Profession in a new light, and it is to be hoped will result in some legislation on the matter. The subject will receive full development in our pages in a short time.—Ed. C. N.]

Sulphuric Acid.

To the Editor of the CHEMICAL NEWS.

SIR,—Some years ago I required a large quantity of pure sulphuric acid, and after some considerable trouble devised a method of preparing it, which afforded me six Winchester quarts daily. Had I required ten times the amount it might easily have been prepared, and if your Subscriber will communicate with me, we may come to an arrangement on the subject.—I am, &c.

JOHN HENRY PEPPER.

Laboratory, Marylebone Institution,
17, Edward Street, Portman Square.

Chemical Notices from Foreign Sources.

TECHNICAL CHEMISTRY.

Green Colours.—Some green colours free from the objections which apply to the arsenical greens are described by Elsner (*Elsner's Chem.-Tech. Mittheil. für 1859-60. Polytech. Centralb. 1861, s. 494*). The first called "Elsner"

green," is made by adding to a solution of sulphate of copper a decoction of fustic, previously clarified by a solution of gelatine; to this mixture is then added 10 or 11 per cent. of protochloride of tin, and lastly an excess of caustic potash or soda. The precipitate is then washed and dried, whereupon it assumes a green colour with a tint of blue.

The "Tin-copper Green" is a stannate of copper, and possesses a colour which Gentele states, is not inferior to any of the greens free from arsenic. The cheapest way of making this, is to heat fifty-nine parts of tin in a Hessian crucible, with 100 parts nitrate of soda, and dissolve the mass when cold in a caustic alkali. When clear, this solution is diluted with water, and a cold solution of sulphate of copper is added. A reddish-yellow precipitate falls, which on being washed and dried, becomes a beautiful green.

Titanium Green was first prepared by Elsner in 1846. It is made in the following way:—Iserin (titaniferous iron) is fused in a Hessian crucible with twelve times its weight of sulphate of potash. When cold, the fused mass is treated with hydrochloric acid, heated to 50° C. and filtered hot; the filtrate is then evaporated until a drop placed on a glass plate solidifies. It is then allowed to cool, and when cold, a concentrated solution of sal-ammoniac is poured over the mass, which is well stirred and then filtered. The titanic acid which remains behind, is digested at 50° or 60° with dilute hydrochloric acid, and the acid solution, after the addition of some solution of prussiate of potash, quickly heated to boiling. A green precipitate falls, which must be washed with water acidulated with hydrochloric acid, and then dried under 100° C. Titanium green then forms a beautiful dark green powder.

Platinum Coating for Porcelain Crucibles.—Elsner gives the following (*Elsner's Chem. Tech. Mittheilungen*, 1859-60, s. 124) as a method by which a strong covering of metallic platinum may be given to porcelain vessels. Platinum-black is rubbed up with oil of turpentine, and the mixture is painted over the object to be coated, made red-hot. The vessel coated is then enclosed in a capsule, and well burnt in a furnace, after which it will be found perfectly covered with a strongly fixed covering of metallic platinum.

Platinum black was found to be fusible in the strongest heat of the furnace oven in the Royal Porcelain Manufactory at Berlin.

Manufacture of Pure Phosphoric Acid.—Dr. J. Neustadt publishes (*Dingler's Polytech. Journal*, Bd. clix. s. 441) an "improved method of making pure phosphoric acid on the large scale." The process involves the preparation of phosphate of soda from bone ash, the formation of phosphate of baryta from this, and the subsequent decomposition of the last by sulphuric acid. In the first place, one part of finely powdered bone ash is mixed with four parts of water and one part hydrochloric acid. After standing six hours, the clear liquid is poured off, and to it is added a boiling solution of sulphate of soda. The sulphate of lime is allowed to deposit, the liquor is poured off, and the precipitate washed and pressed. The liquor decanted, which contains acid phosphate of soda, chloride of sodium, and some sulphate of lime, is now boiled with carbonate of soda and rendered neutral, and then filtered from the precipitated carbonate of lime. We have now a neutral solution of phosphate of soda and chloride of sodium, to which is added just enough of a hot solution of chloride of barium to precipitate the phosphoric acid in the form of phosphate of baryta. Twice the weight of the bone-ash operated on, the author says, is the quantity of chloride of barium required. After well washing, the phosphate of baryta (prepared from one part of bone-ash) is mixed with one part of sulphuric acid diluted with three parts of water, and stirred occasionally for two or three

days, until no sulphuric acid is found in the liquor, which is then strong and pure phosphoric acid.

White Gunpowder.—Dr. J. J. Pohl has improved on Augendre's white gunpowder (*Sitzungs. der Akad. der Wissenschaft zu Wien*. Bd. xli. s. 634). He prescribes the following quantities:—

Ferrocyanide of potassium . . .	28 parts
Cane sugar	23 "
Chlorate of potash	49 "

100

which give a well-burning powder, and nearly approaches the proportions

The results of the combustion of this mixture he calculates to be: 2 K Cy + 3 K Cl + Fe C₂ + N + 6 CO + 6 CO₂ + 14 HO: or 100 parts by weight of the powder is resolved into

47.44 gaseous bodies
52.56 solid residue

100.00

The volumes of the gaseous bodies he estimates as follows:—

Nitrogen	1927.0 C. C.
Carbonic oxide	8942.9 "
Carbonic acid	8942.9 "
Steam	20867.6 "

40680.4 C. C.

Compared with ordinary gunpowder, considered as unity, the results are said to be:—

	Ordinary Powder.	White Powder.
Volume of gas set free.	1	2.107
Temperature of flame	1	0.641
Residue	1	0.77

It should seem, then, that the new powder has over the old the advantages of greater power, igniting at a lower temperature, and leaving less residue. The author points out several other advantages: the ease with which the white powder is manufactured, there being no necessity for granulating and glazing, and the less danger of accidents. The higher price of the materials he considers is more than compensated for by the smaller quantity required.

A political and literary contemporary who dabbles a little in science, and who describes the above composition as being *equally white and cleanly with common gunpowder*, dismally prophesies innumerable accidents if white powder should ever come into use, in consequence of the explosive nature of chlorate of potash—a danger to which he, with wonderful prescience, says, the author has never alluded. As it happens, Dr. Pohl is at pains to show that fears like those of our contemporary are groundless. Only, he states, the heaviest stroke of iron upon iron is sufficient to produce an explosion, and that it is impossible to ignite the powder by rubbing it between wood and metal, or between stones.

ANALYTICAL CHEMISTRY.

Estimation of Carbon in Organic Substances.—Dr. W. Knop proposes (*Chem. Centralblatt*, No. 2, 1861, s. 17) the following improvement on Brunner's method of estimating carbon, in the moist way. He found that when organic matter was heated with a solution of chromic acid, the carbonic acid was evolved so rapidly that it was imperfectly dried in the chloride of calcium tube, and not all taken up in the potash bulbs. He, therefore, first collects the gas in an india-rubber bag, and then passes it quietly through the chloride of calcium, and into the potash apparatus. This is done by fitting up a flask with two tubes bent at right angles, the end of one of these tubes is drawn out and closed; the end of the other is fitted to the india-rubber bag, which must be of an elliptical shape,

and open at both ends, that end adapted to the chloride of calcium tube being shut for the time by a clip. The substance to be analysed is then placed in the flask with a cold mixture of diluted sulphuric acid and bichromate of potash. Heat is now applied to the flask, whereupon carbonic acid is given off, and passes into the bag. When the decomposition is ended the clip is removed, and the gas is gently forced through the chloride of calcium tube and into the potash. The closed tube is then connected by means of an india-rubber tube to a gas-holder filled with air (freed from carbonic acid), the end of the glass is broken off within the tube, and air is passed quietly through the apparatus, carrying with it the last traces of the carbonic acid. Dr. Knop says that he has in this way analysed oxalic and tartaric acids, milk, sugar, and other bodies, and obtained the best results.

MISCELLANEOUS.

Royal Institution of Great Britain.—At the General Monthly Meeting, held on Monday, July 1, 1861, William Pole, Esq., M.A., F.R.S., Treasurer and Vice-President, in the Chair, William Beckett, Esq., Alexander John Ellis, Esq., Hardinge Giffard, Esq., and Joseph Neuberg, Esq., were elected Members of the Royal Institution. John Dobie, Esq., W. H. Stone, Esq., and D. J. Wainwright were admitted Members of the Royal Institution. The Secretary announced that the Fullerian Professorship of Physiology was vacant, and that the Managers would appoint a Professor on May 12, 1862. The presents received since the last meeting were laid on the table, and the thanks of the Members returned for the same.

The Boiling-points of Different Liquids.—The laws relating to the boiling-points of different liquids at the ordinary pressure of the atmosphere have lately been investigated by Mr. Tate, and the results of his experiments are published in the *Philosophical Magazine*. He has made experiments with solutions containing the chlorides of sodium, potassium, barium, calcium, and strontium; the nitrates of soda, potassa, lime, and ammonia; and the carbonates of soda and potassa. He has found for all these salts that the augmentation of boiling temperature may be approximately expressed in a certain power of the per-centage of the salt dissolved. The salts enumerated may be divided into four distinct groups; namely, first, the chlorides of sodium, potassium, and barium, and the carbonate of soda; second, the chlorides of calcium and strontium; third, the nitrates of soda, potassa, and ammonia; fourth, the carbonates of potassa and nitrate of lime. In each of these four groups, the augmentations of boiling temperature of the solutions have a constant ratio to one another for an equal weight of salt dissolved. He has also ascertained by experiments that for an equal weight of salts, the boiling temperatures are (approximately) in the inverse ratio of the chemical equivalents of their bases, and in the case of the nitrate of lime and the carbonate of potassa with the equivalents of the entire salts. Although the law thus indicated is not strictly true, it is sufficiently exact to warrant further inquiry, and the cases in which it is found to apply are too numerous to be referred to accidental coincidence. Future researches may extend these laws to other substances, as it is quite consistent with analogy to suppose that the chemical composition of a substance affects the boiling temperature of its solution. It will readily be acknowledged that the prosecution of these experiments may throw additional light upon the generation of steam, the economy of fuel, and kindred questions of great practical importance to engineers.

Artificial Manure from Newfoundland.—Manure, which may now be considered as an article of Newfoundland trade, is manufactured on Massacre Island, at St. Pierre's, in the following manner:—Old herring bait, at a cost of two francs per barrel, is salted with foreign salt, then boiled in a furnace, containing 250 gallons, for three hours; when cold, put into thick round mats, made for the purpose, about two feet in diameter, then placed under a screw, about twelve of them at a time, for twenty hours, by which process the water and oil are pressed out; these run by means of a shallow trough and conducting spouts, to casks outside the building, after which the oil floats, and is taken off, yielding about five per cent.; the mats containing the herring are put out, after pressing, to dry for two days: it is then taken from the mats, put into flour barrels, and closely packed by treading upon it; some is put into boxes containing 224 lbs. each; the barrel contains about the same weight. Caplin are made into manure as above, but do not produce oil. Cods' heads, also in the same manner. Cods' heads are also well dried on a beach, for five days or a week, without any salt. They are then packed into flour barrels, screwed in and sent to France, where they are ground up for manure. All these manures are said to be better than guano, and fifty per cent. higher in price. Mussels, oysters, bones, kelp—I saw specimens of all these manures, ground to a powder, said to be equally as good as any other kinds. In the manufactory, which is about sixty feet long by forty wide, I saw thirty screws fixed in frames, over troughs, say five in each frame. Forty men were here employed last year, but now less, on account of some having been lost coming out the last spring; the establishment could manufacture twenty tons per day with more room. Three hundred tons are sent to France; the island is not large enough to carry it on to the extent desired. There are no mills at present for grinding, but it is intended to import some next year, and fully complete the manufactory at St. Pierre's. If these manures pay and answer at so great a distance as France, why should they not answer the inland agriculture of Newfoundland?

ANSWERS TO CORRESPONDENTS.

"* In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Vol. III. of the *CHEMICAL NEWS*, containing a copious Index, is now ready, price 10s. 8d., by post 11s. 4d., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our Office, price 1s. 6d. Subscribers may have their copies bound for 2s. if sent to our Office, or, if accompanied by a cloth case, for 6d. A few copies of Vols. I. and II. can still be had, price respectively, 10s. 6d., and 12s., or by post 11s. 2d. and 12s. 8d. Vol. IV. commenced with No. 83 on July 6, 1861, and will be completed in 26 numbers.

The New Part for June (published June 1) is also ready, price 1s. 9d.

Binding Vol. III.—A Subscriber is informed that there is not the slightest necessity to bind up any of the advertisement pages with the matter of the volume. None of our own volumes are so bound, and no intelligent binder would, unless expressly ordered to do so, bind up any advertisement pages, they being printed, paged, and folded with the express purpose of being left out of the bound volume.

The Coal-Tar Colouring Matters.—In answer to numerous applications, we beg to state that the number of the *CHEMICAL NEWS* containing Mr. Perkin's lecture on Colouring Matter can be had on application at the Office.

R. S. T.—Cotton and Johnson, Grafton Street, Soho, or Johnson and Matthey, Hatton Garden, will supply you.

E.—Distill it by means of steam, keeping the temperature below 212° F.

Alimentum Salutaris.—We shall always be happy to receive letters from this correspondent, but we have an objection to reprinting letters which have already appeared in contemporary journals.

Chemicus Junius.—You are quite correct in saying that the popular process for detecting alum in bread will show its presence if alum be there. It is however open to the objection that it is equally certain to show the presence of alum when none is in the bread.

Out Flowers.—A little camphor in the water will preserve cut flowers for some days longer than if plain water were used.

THE CHEMICAL NEWS.

VOL. IV. No. 84.—July 13, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Weighing of Moist Precipitates,
by FERDINAND F. MAYER.

MR. CH. MÈNE, of Creusot (*Journ. de Pharm. et de Chimie*, Oct., 1858) gives a mode of weighing which does away to a great extent, with the tediousness and difficulties attending the drying of many precipitates, especially in volumetric analysis. He washes the precipitate thoroughly by decantation, and then introduces it carefully into a bottle, the exact weight of which, when filled with distilled water at a certain temperature, is known. Since the precipitate is heavier than water, the bottle when filled again will weigh more than without the precipitate, and the difference between the two weights furnishes the means of calculating the weight of the precipitate.

In case the precipitate settles but slowly, it may be collected on a filter, and, together with the filter, after washing, be introduced into the bottle, in which case the weight of the filter and its specific gravity, supposing any difference should exist between its own and that of water, is to be taken in account. Precipitates soluble in or affected by water may be weighed in some other liquid.

This method, of which the above are the outlines, is spoken of in the *Jahresbericht der Chemie* for 1858 in rather disparaging terms, and I consider it not more than justice to the method, if not also to Mr. Mène, to prove its correctness, the more so as I have applied the principle on a large scale as far back as 1855.

I engaged in that year in the manufacture of carbonate of lead from refuse sulphate of lead, by treating the latter, in a pulpy condition, with carbonate of soda. The sulphate of lead I used contained very varying proportions of water and soluble impurities, from which latter it had first to be freed by washing. It was then in the state of a thin pulp, and the difficulty was to find the amount of the dry sulphate of lead, as it was a matter of importance to use as little carbonate of soda, and to obtain as pure a carbonate of lead and sulphate of soda as possible. This could only be done by weighing it as whole, or in portions, but as the drying of a tubful of sulphate of lead (from 500 to 1200 lbs.) was impracticable, and sampling not less so, since the upper strata contained a much larger proportion of water than the lead at the bottom; I contrived the following method, which enabled me to leave the management of the process in the hands of a workman:—

I took a strong oaken pail, weighing 8 lbs. when empty, and caused a black mark to be burnt in horizontally around the inside of the pail, two inches below the rim, up to which mark it held 20 lbs. of water. I reasoned as follows:—The specific gravity of sulphate of lead being 6.3, the pail, if filled up to the mark,

would hold 126 lbs. of pure sulphate of lead. The specific gravity of water being 5.3 less than that of sulphate of lead, it followed that if there was 1 lb. of water in the pailful of moist sulphate, the pail would weigh 5.3 lbs. less than 126 (+8, the tare of the pail) = 120.7 (+8); if there were 2 lbs. of water present, the weight would be 115.4 (+8), and so on. This enabled me to calculate a table, giving in one column the actual weight of the pail when filled with moist sulphate, and opposite, in a second column, the amount of dry sulphate corresponding to the gross weight. The weight of dry sulphate was thus found as accurately as could be desired, although the amounts varied in practice from 30 to 105 lbs.

It is nothing but an application of the Archimedean theorem, that when a solid body is immersed in a liquid it loses a portion of its weight, equal to the weight of the fluid which it displaces, or to the weight of its own bulk of the liquid.

This, as I suppose, is precisely the principle applied by Mr. Mène. The precipitate he obtains by a certain chemical manipulation is a substance of known composition and specific gravity. Supposing it to be sulphate of lead, and the bottle, when filled with water at the normal temperature, to weigh 70 grammes = 50 grammes of water, and 20 for tare. After introducing the precipitate and filling again with water it weighed 71.06 grammes. Now, as the specific gravity of sulphate of lead is 6.3, or as the weight of a cubic measure of sulphate of lead is 6.3 times that of a cubic measure of water, and as the space of one part by weight of water is taken up by 6.2 parts by weight of sulphate of lead, it follows that the quantity of sulphate of lead in the bottle, which has taken up the space of one part by weight of water, increases the original weight of the bottle (filled with pure water) by 5.3. To find the amount of water displaced, it is only necessary to divide the overweight (1.06 grammes) by 5.3 = 0.2, which, added to the overweight 1.06 + 0.2 gives 1.26 grammes as the weight of the precipitate.

Hence the rule, which is of great convenience in volumetric analysis, that to find the weight of a moist precipitate, which is a compound of known specific gravity, weigh it in a specific gravity bottle or some other vessel of known weight, when filled with water, or any other liquid, at the normal temperature, again fill it with the water or other liquid, divide the excess of the new weight by the specific gravity of the substance, less that of the water or other liquid (that of water being = 1), and add the quotient to the overweight, which gives the weight of the precipitate.

The Editor of the *Jahresbericht* appears to have overlooked the fact that the precipitates weighed in this manner are definite compounds, the specific gravity of which is well ascertained.

The principle I have exemplified above may not be novel; but as I have never met with it, chemists, as well as manufacturers, especially of colours, will probably

also find it of interest, and certainly highly practicable and easy of execution.—*Am. Journ. Science and Arts.*

Boracic Acid in the Sea-water of the Pacific on the Coast of California, by JOHN A. VEATCH.

THE existence of boracic acid in the sea-water of our coast was brought to my notice in July, 1857. I had, in the month of January of the previous year, discovered borate of soda and other borates in solution in the water of a mineral spring in Tehama County, near the upper end of the Sacramento Valley. Prosecuting the research, I found traces of boracic acid—in the form of borates—in nearly all the mineral springs with which the State of California abounds. This was especially the case in the coast mountains. Borate of soda was so abundant in one particular locality that enormous crystals of that salt were formed at the bottom of a shallow lake, or rather marsh, one or two hundred acres in extent. The crystals were hexahedral with bevelled or replaced edges, and truncated angles; attaining the size, in some cases, of four inches in length by two in diameter, forming splendid and attractive specimens. In the same neighbourhood, a cluster of small thermal springs were observed holding free boracic acid in solution. A few hundred yards from these, a great number of hot springs, of a temperature of 212° F., rose up through the fissures of a silicious rock. These springs held a considerable quantity of borax, as well as free boracic acid. Many other localities furnished similar indications, but in a less extensive form.

In progress of the examination I found that the common salt (chloride of sodium) exposed for sale in the San Francisco market, and which, it was understood, came from certain deposits of that article on the seashore in the southern part of the State, also furnished boracic acid. I was led to attribute it to the fact of mineral springs emptying into the lagoons furnishing the salt. It was, therefore, a matter of no small surprise, when on a visit to the localities, I found no trace of acid in any of the springs in the adjacent district. This led to an examination of the sea-water, and a detection of an appreciable quantity of boracic acid therein. It was at Santa Barbara where I first detected it, and subsequently at various points from San Diego to the Straits of Fuca. It seems to be in the form of borate of soda, and perhaps of lime. The quantity diminishes toward the north. It is barely perceptible in specimens of water brought from beyond Oregon, and seems to reach its maximum near San Diego.

This peculiarity seems to extend no great distance seaward. Water taken thirty or forty miles west of San Francisco gave no trace of acid. In twelve specimens taken at various points between this port and the Sandwich Islands, furnished me by Mr. Gulick, of Honolulu, only that nearest our coast gave boracic acid. In ten specimens kindly furnished me by Dr. W. O. Ayers, taken up by Dr. J. D. B. Stillman, in a trip of one of the Pacific mail steamers from Panama to this place, no acid was discovered south of the Cortez Shoals.

I have not as yet been able to obtain specimens of water south of San Diego, nearer the shore than the usual route of the mail steamers. Neither have I been able to test the breadth of this boracic acid belt any further than the fact above stated, of no acid being found at the distance of thirty or forty miles west from the Golden Gate. I think it probable that it is confined within the submarine ridge running parallel with the

coast, the southern portion of which is indicated by certain shoals and island groups. The source of the acid is undoubtedly volcanic, and the seat of the volcanic action is most likely to exist in this submerged mountain range. It strengthens the probability of the eruptive character of the Cortez Shoal.

I hope in future to be able to make more accurate and extended examinations, unless some one more capable of doing justice to the subject should take it in hand. With this view, I solicited the attention of Dr. J. S. Newberry to these facts while he was in this city, on his way to join Lieutenant Ives' Colorado Exploring Expedition, hoping he might think it worthy of investigation during his stay on this coast.—*Proc. Cal. Acad. Nat. Sci.*

TECHNICAL CHEMISTRY.

On the Origin and Progress of the Phosphorus and Match Manufactures, by G. GORE.

IT has been wisely remarked, that Science "teaches us to be neglectful of nothing; not to despise small beginnings, for they precede, of necessity, all great things in the knowledge of science, either pure or applied." Not only should we not neglect scientific knowledge, but we should nurse as it were the smallest scientific truth; trying and watching the influence of various conditions upon it; increasing its distinctness or importance by modifying the surrounding circumstances; adding here a little and there a little, in order to magnify the extent or variety of its applications to human benefit. It is by such processes of treatment as this, slow and certain, that the little facts of the bygone alchemists, and of the more modern scientific investigators, have been extended and elaborated into the marvellous and magnificent realities of the present day.

Nearly all the great practical results of science of this period have had their origin in apparently useless and out-of-the-way observations. The expansive power of steam was known long before it was applied to any useful purpose. One observed and another observed the influence of various circumstances upon it; one invented and another contrived additional means of controlling it and directing it; one added and another introduced contrivances and pieces of accessory mechanism to increase its power; until from the simple and apparently useless fact of vapour expansion, it has grown to be the giant power of the earth, influencing the actions and habits of nearly all mankind.

The curious facts respecting the action of liquids on metals, observed by Volta and Galvani, and the action of electric currents on magnets, have, by the repeated trials and applications of subsequent discoverers and inventors, been elaborated into the present system of electro-telegraphy, which bids fair to cover the whole earth with its wires and to bring every human being into speaking distance with each other.

No reasonable and intelligent person can compare the commencements of these things with their present developments without being impressed with the insignificance of their origin and the magnificence of their practical results, nor without being convinced of the importance of abstract scientific investigation. It is not my object on the present occasion to dilate upon the relations of abstract science to manufactures and practical life, but to give some account of the origin, progress, and present condition of the phosphorus and match manufacture.

In the year 1669 phosphorus was accidentally discovered in human urine as "a dark, unctuous, daubing mass," by Brandt, a merchant and alchemist, of Hamburg, while searching for a liquid capable of transmuting silver into gold. By some means it appears that at the same time Kunckell, a German chemist, gained some knowledge of the means of obtaining this substance, and communicated it to Kraft, of Dresden, who proceeded to Hamburg and paid 200 dollars for a specimen "for him to make demonstrations to princes." Kunckell prepared some of the substance and exhibited it to the Courts of Saxony and Brandenburg, although it was not a very delicate or agreeable exhibition, "because the unctuous and daubing oyliness was not yet accurately separated from it, and, without doubt, it was very stinking, and therefore unpleasant." He also gave some to his friends, Professors in Germany, and to Mr. Linck, of Leipzig, for sale. An account of it was published in his "Laboratorium Chymicum," Hamburg and Leipzig, 1716, p. 660.

To afford some idea of the effect of Brandt's discovery upon his fellow-townsmen and upon alchemists generally I quote the following:—"When, now, such like noble motives made that good old man Brandt to broil and to sweat much more by his exorcements, one may easily guess how much at that time the whole heaven of Hamburg did hang full of fiddles as he brought forth out of it a lumen which, in the world, is counted the most perfect *agens intrinsicum*. There was then cried nothing but triumph and victory among the chymists. Those good people erected already in their thoughts so many hospitals and poor-houses that no beggar should ever more molest any man in the streets, made great legacies, and pious causes, and what not else." "Besides, the other alchemists did encourage him yet more, and desisted not to make him believe how this was that same fiery ghost of Moses that in the beginning moved upon the water, yea, his splendid shining face: the fiery pillar in the desert, that secret fire of the altar wherewith Moses burned the golden calf before he strewed it upon the fire and made it potable."

About the year 1670 the Honourable Robert Boyle, an Irishman and a philosopher of this country, brought over from Germany a youth named Ambrose Godfrey Hanckwitz to assist him in his chemical experiments, and having obtained information from Saxony of the method of extracting phosphorus, directed his assistant, Mr. Bilger, to instruct Hanckwitz to prepare some of it. Hanckwitz it appears succeeded in preparing an ounce of the substance and presented it to his master even before he received the instructions from Mr. Bilger. He was now sent by Boyle on a tour through "Holland, Italy, Naples, and Germany," to gain further information respecting "the marvellous lumen," but with little success, for he returned without meeting with "even one that could make even that poor daubing stuff as Kunckell's out of the usual microcosmical matters."

In No. 135 of the *Philosophical Transactions* of the Royal Society, dated March 26, 1677, page 87, is a paper by Boyle, entitled, "An Account of Four Sorts of Facitious Shining Substances, communicated to the publisher from very good hands, both in printed papers and in letters not printed." After speaking of three sorts, it says:—"The other is Phosphorus Fulgurans, which is a matter, made both in a liquid and dry form, and not only shineth in the dark and communicates a sudden light to such bodies as 'tis rubbed upon, but being included in a glass vessel, well closed, doth now and then fulgurate, and sometimes also raise itself as 'twere into

waves of light. Differing from the Balduinian stone, which is to be exposed to some shining body, as the day, the sun, the fire, or some lighted candle, to receive light from these, whereas this fulgurating substance carries its light alwaies with it, and when put in a dark place presently shews the same. Of which we have this further assurance given us, that a little portion of it having been kept two whole years hath not yet lost its power of shining. So that 'tis believed if a considerable big piece were prepared of it, it would serve for a perpetual, or, at least, a very long lasting light."

In No. 150 (August 10, 1683), p. 289, is also given "An Account of some Experiments made at several meetings of the Royal Society by the ingenious Frederick Slare, M.D., F.R.S., and one of the Royal Collège of Physicians, with some short applications of them to physical matters." He gives "A Parrallel betwixt Lightning and a Phosphorus," and relates a number of experiments of adding phosphorus to oil of vitriol, water, oil of turpentine, and oil of petroleum, producing combustion, &c.

And in No. 196, p. 579, dated January, 1693, is "A paper of the Honourable Robert Boyle's, deposited with the Secretaries of the Royal Society, October 14, 1680, and opened since his death, being an account of his making phosphorus, &c." "September 30, 1680. There was taken a considerable quantity of man's urine (because the liquor yields but a small proportion of the desired quintessence), and of this a good part at least had been for a pretty while digested before it was used. Then this liquor was distilled with a moderate heat, till the spirituous and saline parts were drawn off, after which the superfluous moisture also was abstracted (or evaporated away), till the remaining substance was brought to the consistence of a somewhat thick syrup, or a thin extract. This done, it was well incorporated with thrice its weight of fine white sand, and the mixture being put into a strong stone retort, to which a large receiver (in good part filled with water) was so joyn'd that the nose of the retort did almost touch the water. Then, the two vessels being carefully luted together, a naked fire was gradually administered for five or six hours, that of that was either phlegmatick or volatile might come over first. When this was done the fire was encreased, and at length for five or six hours was made as strong and intense as the furnace (which was not bad) was capable of giving (which violence of fire is a circumstance not to be omitted in the operation). By this means there came over good store of white fumes, almost like those that appear in the distillation of oyl of vitriol; and when those fumes are passed and the receiver grew clear, they were after a while succeeded by another sort, that seemed in the receiver to give a faint, blewish light, almost like that of little burning matches dipped in sulphur. And, last of all, the fire being very vehement, there passed over another substance that was judg'd more ponderous than the former, because it fell through the water to the bottom of the receiver, whence being taken out (and partly even whilst it stay'd there), it appeared by several effects and other phenomena to be such a kind of substance as we desired and expected."

Hanckwitz, the servant of Boyle, and working under his direction, at the laboratory in Southampton Street, London, succeeded, by his own skill, and perseverance, in considerably improving the process or manufacture, and produced phosphorus in larger quantities than any other person. He confirmed the opinion of his master, that it required an intense heat for its extraction; he

states, "for in truth and fact it is not a work for gentlemen and cabinet chymists, but there is required for it an operator well versed in fires, to whom its mechanick and manipulation is well known." In an advertisement he states:—"For the information of the curious, he is the only one in London who makes inflammable phosphorus which can be preserved in water. Phosphorus of Bolognian stone, flowers of phosphorus, black phosphorus, and that made with acid oil, and other varieties. All unadulterated; every description of good drugs. He sells wholesale and retail. N.B. He sells solid phosphorus, wholesale, fifty shillings an ounce, and retail, three pounds sterling the ounce."

In a "Historical Sketch of the Progress of Pharmacy in Great Britain, by Jacob Bell," it is stated, that "A house and shop, with a laboratory, were built on the Bedford estate, in the year 1706, by Ambrose Godfrey Hanckwitz, who had carried on business as a chymist in the neighbourhood since 1680. He was a maker of phosphorus and other chemicals, which were rare at that period, and which he sold in different parts of the country during his travels. His laboratory was a fashionable resort in the afternoon on certain occasions, when he performed popular experiments for the amusement of his friends. It opened with glass doors into a garden, which extended as far as the Strand, but which is now built upon. Four curious old prints of the laboratory in its former state are in the possession of its present proprietors, Messrs. Godfrey and Cooke, of Southampton Street, Covent Garden, also a portrait of Ambrose Godfrey Hanckwitz, engraved by George Vertue (1718), which he had distributed among his customers as a keepsake."

(To be continued.)

Products from the Combustion of Gunpowder under Different Pressures, by B. F. CRAIG.

THE perusal of the paper of Bunsen and Schiskoff on "The Chemical Theory of Gunpowder," whose publication about two years ago attracted much attention (*American Journal of Science and Arts* [2], xxvi. 106), led me, as it no doubt did others, to make some experiments on the residues of exploded powder.

The investigations of the above-named chemists were made on the products of gunpowder which had been burned in small quantities, and under very slight pressure, and, in concluding their paper, they advance the supposition that, under a difference of circumstances, the products may be essentially different from those which were obtained by themselves.

Such is actually the case, for the solution obtained by washing a gun with well-boiled distilled water, immediately after its discharge, and filtering while hot, will be found to contain sulphuret of potassium, with very small quantities of other substances, while Bunsen and Schiskoff found their residues to consist mainly of sulphate and carbonate of potash. This difference is what was to be expected from our knowledge of chemical laws; and it is also to be observed that the products of combustion in the gun vary somewhat according as the explosion takes place under a greater or less pressure. Thus, in firing with a shot very heavy in proportion to the charge of powder, as in firing a mortar, the washings of the piece are found to be of a bright green colour, while the ordinary washings of a gun are colourless after the suspended carbon has been allowed to settle, or has been removed by filtration.

The colour above spoken of is exactly the tint of a solution of a sesquisalt of chromium; it is not impaired by filtration of the liquid, but disappears in a few hours by exposure to the air, and immediately by the action of acids. The cause of this colour seemed to me at first obscure, but I found that by adding a very minute quantity of freshly precipitated sulphuret of iron to solution of protosulphuret of potassium, the same colour was produced, and a sensible trace of iron may always be found in gunpowder.

A greenish colour is frequently observed when sulphuret of iron is precipitated in the presence of an alkaline sulphuret, but as it disappears on standing, it has been commonly attributed to the presence of particles of sulphuret of iron held in suspension, an opinion which must be erroneous, since I have obtained a solution of iron in sulphuret of potassium of an intensely green colour, perfectly clear and transparent, and permanent for many days in a sealed tube.

Why this green compound should be formed under some circumstances, and not under others, in a mortar, and not in a cannon, is not insusceptible of explanation.

It has been shown that when powder is exploded under slight pressure the alkaline metal remains in large part as a sulphate, but under higher pressure, and corresponding temperature, it is reduced to the condition of a sulphuret. Now, by analogy, it would seem, that with the ordinary charges of a cannon or musket the iron is not reduced to the state of sulphuret, but if, as is often the case in a mortar, the projectile is fifty times the weight of the powder, or upwards, the gases are brought to a state of great tension before the shot moves, and in that state of things the carbon is completely converted into carbonic acid, and the iron, as well as the potassium, brought to the condition of sulphuret.—*American Journal of Science and Arts.*

On the Solidification of Carbonic Acid, by MM. A. LOIR and CH. DRION.

IN a paper read before the Academy, June 2, 1860, we stated that atmospheric pressure liquefies carbonic acid when its temperature is reduced to the point at which liquid ammonia evaporates *in vacuo*. By slightly modifying the conditions of the experiment, we have succeeded in solidifying carbonic acid with the aid of an apparatus as simple as those daily employed in chemical laboratories. This hitherto dangerous and costly operation may in future be easily repeated to a chemical class.

If liquid ammonia is introduced into a glass globe, and the interior of this put in communication with a good air-pump, by the intervention of a vessel containing coke impregnated with sulphuric acid, the temperature of the liquid is rapidly reduced from the first strokes of the piston. The liquid begins to solidify towards -81° ; it soon becomes a mass, and if the air-pump allows the reducing of the pressure to about a millimètre of mercury, the temperature of the solid ammonia becomes lowered some degrees more and reaches -89.5° . This suffices to determine the liquefaction of carbonic acid under atmospheric pressure. We have, in fact, proved that carbonic gas liquefies by passing a current of the dry carbonic acid gas into a small U shaped tube, immersed in ammonia; but as the temperature obtained is only a few degrees below that of saturation, we get only a small quantity liquefied. If, on the contrary, a slight elevation of pressure is employed, the experiment becomes easy, and yields in a short time notable quan-

tities of solid carbonic acid. The following is the manner of operating:—Introduce about 150 cubic centimetres of liquid ammonia into a reversed glass receiver, the sides of which are cemented to a plate with two holes. In the central opening fit a glass tube, closed internally, and reaching the bottom of the receiver, the other opening serving to place the interior of the receiver in communication with the pneumatic machine. Carbonic acid is produced by heating previously-dried bicarbonate of soda in a copper retort, the neck containing fragments of chloride of calcium. One part of this retort communicates by a leaden tube on one hand with the tube which is immersed in liquid ammonia, on the other hand with a small manometer of compressed air. The air being previously expelled from the apparatus, and the temperature of the ammonia lowered to about the point of solidification, the retort is heated, noting meanwhile carefully the pressure. The pressure is thus maintained between three and four atmospheres. Rapidly augmenting transparent crystals soon appear on the sides of the interior tube, so that in about half-an-hour all that portion of the tube which is plunged in ammonia becomes covered with a thick stratum of crystals (about 25 grammes). The experiment may then be concluded and the apparatus dismounted.

Solid carbonic acid, obtained under the above mentioned conditions, appears a colourless mass as transparent as ice. It is easily detached from the sides of the condensing-tube by means of a glass rod; it then divides into large cubic crystals, each side about three to four millimetres. Exposed to the air, these crystals slowly return to their gaseous state; they evaporate, leaving no residue. Placed on the hand, they communicate no immediate sensation of heat or cold; they are with difficulty held in the fingers, and with a slight pressure escape as if covered with an unctuous matter. If one of the crystals is kept between the thumb and forefinger, it soon produces an intolerable burning.

An experiment was performed by placing a certain quantity of solid carbonic acid in a small glass tube communicating with a receiver filled with mercury. After some time the crystals disappeared, leaving no residue, while the receiver was filled with perfectly pure carbonic gas, capable of being completely absorbed by potash. Mixed with ether, in a small porcelain crucible, these carbonic acid crystals yield a freezing mixture of a temperature of -81° .

As a conclusion to these summary indications we will add that the liquid ammonia used in our experiments was prepared by M. Bussy's process,—that is to say, by acting on ammoniacal gas in a globe surrounded with liquid sulphurous acid, the evaporation of which is expedited by an air-pump. By this method nearly two decilitres of liquid ammonia can be easily obtained in less than two hours.

We determined the temperatures here indicated by means of an alcoholic thermometer, on which we marked two fixed points,—that is to say, 0° at melting ice, and -40° at the temperature of melting mercury.—*Comptes Rendus*.

On a Black Varnish for Zinc, by M. BÖTTGER.

M. BÖTTGER describes a process for covering zinc with a chemical, adherent velvet-black varnish. Dissolve 2 parts by weight of nitrate of copper and 3 parts of crystallised chloride in 64 parts of distilled water; add 8 parts of hydrochloric acid of 1.10 density; into this

liquid plunge the zinc, previously scoured with fine sand; then wash the metal with water and dry it rapidly.

This coating constitutes a kind of metallic alloy. It is M. Böttger's opinion, that characters in relief may be executed on a sheet of zinc by using this composition, and by employing dilute nitric acid (1 to 10), as the black coating resists the acid which attacks only the unpreserved metal.—*Journal de Pharmacie et de Chimie*.

Influence of Lithia on Fructification, by M. DE SALM-HOESTMAE.

BARLEY does not develop itself in coarsely-powdered and washed rock crystal; after being watered with water containing carbonate of lime, magnesia and manganese, sulphates, phosphates, and fluoride of potassium, it sent forth a feeble shoot but did not fructify; but by the addition of a trace of nitrate of lithia (a hundredth of a milligramme!) a barley corn flowered, and yielded two perfectly ripe grains.

From this experiment the author insists that lithia is indispensable to the development of grain.—*Annal. der Physik und Chem.*, vol. cxi. p. 644.

PHARMACY, TOXICOLOGY, &c.

On Arsenic-Eating in Styria.

PROFESSOR E. SCHAFER, of Gratz, publishes (*Sitzungsber. der Akad. der Wissenschaft zu Wien*) a few more particulars respecting the arsenic eaters of Styria. The paper seems to be the same as that quoted by Dr. Roscoe (*CHEMICAL NEWS*, vol. ii. p. 261), but contains some particulars which were omitted from our report. At the new moon, it should seem, the use of arsenic is for a time suspended, and then begun again with the smallest dose, which is increased from day to day until the moon reaches the full. The dose is then gradually diminished again, and a dose of aloes is taken occasionally, until strong purging is produced.

Most arsenic eaters observe no peculiarity in their diet, but some avoid fatty food, and the greater number are given to the free use of spirituous liquors. There are some differences of statement as to the form in which the arsenic is taken. In some cases powdered white arsenic is said to be swallowed "in a warm liquid, such as coffee" (*CHEMICAL NEWS*, vol. i. p. 281); but in the case observed by Dr. Knappe, and quoted by Dr. Roscoe, the man took a piece of solid arsenic, crunched it with his teeth, and swallowed it. The urine of this man contained but a trace of the poison, and therefore it is reasonable to suppose that when arsenic is taken in a solid form, on account of its insolubility, the greater part is carried away in the feces.

In the case of a horse, experimented upon by Dr. Koch, arsenic was found in the saliva, blood, urine, and excrement, the largest proportion necessarily in the last. The experiments of Dr. Koch show that the elimination of arsenic by the urine takes place very slowly, and that the poison accumulates in the blood.

On an Improved Method of Preparing Soda Carbonas Siccata, by HARRY NAPIER DRAPER, F.C.S.L.

The directions of the three British Pharmacopœias for the preparation of dried carbonate of soda are in almost every respect alike. Crystals of carbonate of soda are

exposed to the action of heat until the whole of their water is expelled. This process has two disadvantages : 1. The carbonate of soda of commerce, which is always used in practice to the exclusion of the pure product of the *Pharmacopœias*, invariably contains sulphates and chlorides. These are, of course, found also in the dry salt. 2. The hard cake which results from the desiccation of the crystals is extremely difficult to powder, and never makes a really elegant preparation.

Both these inconveniences may be remedied by the substitution of bicarbonate of soda for the carbonate. When this salt is heated to redness it, as is well known, loses one of its two equivalents of carbonic acid and all its water, a pure mono-carbonate remaining. Bicarbonate of soda of commerce is nearly always almost pure, never, as far as my experience goes, containing more than slight traces of chlorides and sulphates. When not heated beyond redness, the resulting carbonate is not hard, but, on the contrary, is a loosely cohering perfectly white powder. The slight difference in the cost of carbonate and bicarbonate is of small moment when compared with the saving of time and trouble, and the superiority of the dried carbonate made from the latter salt.—*Dublin Medical Press*.

PHYSICAL SCIENCE.

On the Boiling-points of Liquids, by M. L. DUFOUR, of Lausanne.

It is an established fact that the temperature of boiling water, instead of being always the same, or varying only with the atmospheric pressure, differs according to the vessel in which the liquid is heated. For instance, water boils sooner in a metal than in a glass vessel, and M. F. Marcet's numerous experiments (*Bibliothèque Universelle*, vol. xxxviii. p. 381) have shown, amongst other things, that the treatment a glass vessel has undergone (as washing in sulphuric acid, &c.) causes several degrees of variation in the boiling point. Water deprived of the air dissolved in it can be re-heated considerably above 100° C. before becoming gaseous, but then it boils violently. Donny, in his interesting experiments (*Annales de Chimie, et de Physique*, third series, vol. xvi. p. 167), carefully heated water completely freed from air, to 135° before a change of condition took place. This retardation of ebullition is manifested also by other liquids, and the production of vapours by starts is a frequent sign of it in glass vessels.

In the actual state of things, boiling produced at a higher temperature than that at which the elastic force of the vapour of the liquid is equal to the external pressure is generally considered as an anomaly due to two causes,—firstly, the adhesion of the liquid to the substance of the vessel; secondly, the absence of air in solution. There are, however, some curious facts, which show that the adhesion of a solid and the absence of air in solution are inadequate to explain the retardation in boiling; but, on the contrary, contact with a solid produces an immediate and decided formation of vapours. If a few drops of water are dropped into linseed oil, heated to 105° or 110° in a porcelain capsule, they fall slowly to the bottom of the vessel. The instant they reach it vapour is formed suddenly; the slightly-diminished drop of water rebounds several millimètres from the bottom, then falls again, causing another disengagement of vapour; again it rises, and so on. Now, it must

be remarked that the drops of water, while floating in the oil, before touching the bottom of the vessel, undergo no perceptible evaporation, and that it is only on their contact with a solid that there is a sudden production of a bubble of vapour.

It will, then, be asked, What would happen were the water while being heated, kept away from the sides of the vessel, floating freely in a medium of a density equal to its own? The proper medium to be employed in these experiments ought to be able to bear temperatures above 100° without boiling, to be about the same density as water, and not to mix with water. Oils will not do, but certain essences sufficiently fulfil these conditions.

Essence of cloves, with a little oil added, forms a liquid in which water maintains its equilibrium in perfectly rounded drops, and moving about freely in the interior. Carefully heated, the mixture always passes 100° C, and sometimes goes much higher before the water boils. It is easily and constantly raised to 120° , 130° , and even higher. I have many times raised the temperature of aqueous globules of ten millimètres in diameter, to 140° and 150° . Minute globules, from one to two millimètres in diameter, have several times reached 170° , and even 175° ,—that is to say, to temperatures at which the elastic force of aqueous vapour is more than eight atmospheres. I am speaking here of water which has undergone no preparation, which has been neither distilled nor freed from air. At these high temperatures the globules do not undergo, as might be imagined, slow and continuous ebullition; they are as quiet and limpid at 150° as at 10° ; it is rather the liquid state continued much beyond the limits corresponding to the pressure under which the operation is performed.

Ebullition is produced when the globules come in contact with a solid. If, drawn by the currents, which heating inevitably occasions, they strike against the sides of the vessel or the bulb of the thermometer, there is suddenly formed a bubble of vapour; the globule, become rather smaller, is projected violently from the point at which it produced this kind of explosion, and then continues floating in the medium. The result is the same if, when the temperature is above 115° or 120° , a globule is touched with a glass or metal rod; an explosion is produced at the point of contact, a bubble of vapour is disengaged and passes through the essence, and the globule touched rebounds as though the solid point exercised a sudden repulsion over it. However, all solids are not equally efficacious in producing this change of state; glass or metal rods sometimes fail, but a slender wooden or charcoal stick always incites an immediate and tumultuous ebullition in the middle of the overheated globules. Contact with saline crystals is generally very efficacious.

It is difficult to preserve large globules from contact with the sides; hence they are the seat of the formation of vapour on one point of their surface, which has the effect generally of breaking them up into smaller globules. In my experiments, the vessels employed were small glass globes, and I have already easily obtained a globule of eighteen millimètres, at 130° C., and others of six to ten millimètres at 150° C., &c. The smallest globules most readily escape contact with the sides, and can be submitted to a higher temperature.

It may well be supposed that the preceding facts may be realised with other liquids if heated under proper conditions. This supposition is confirmed by the experiments I am now making. For instance, chloroform, heated in a concentrated solution of chloride of zinc,

easily reaches 90° and 100° . The chloroform globules float lightly in this liquid, like water globules in essence of clove. Beyond 70° contact with a solid rod produces decided and violent evaporation.

It is difficult not to connect these facts with those in which contact with a solid causes the crystallisation of super-saturated saline solutions, and also the sudden solidification of water, sulphur, &c., when brought below their ordinary temperature for solidifying. It is equally difficult to disconnect them from the facts which I have lately had the honour to bring before the Academy,—facts which showed that liquids resist solidification when immersed in a fluid medium. It appears that contact with a solid determines a change of state in liquids, and it may be that the limits of temperature assigned to the various conditions of bodies are not so absolute as they seem. Our experiments on liquids always made in vessels in contact with solid bodies may perhaps have led us wrongly to consider, as inherent properties of the liquids themselves, the phenomena resulting, at least in part, from the presence of solids. Thus, when water floats freely in a fluid it rarely freezes at 0° , and it is only changed into vapour at a point of the thermometric scale always exceeding 100° .—*Comptes Rendus*.

Researches on the Chemical Action of the Spark from Ruhmkorff's Induction Apparatus, by M. ADOLPHE PERROT.

THE following results have been obtained by the author in a lengthened examination of the chemical action of the spark of Ruhmkorff's induction apparatus. The complete paper appears in the *Annales de Chimie et de Physique*, series 3, vol. lxi. pp. 161—199.

1. Discharges by the direct current from Ruhmkorff's apparatus decompose aqueous vapour.

2. Induction sparks combine or decompose gases or vapours more energetically than sparks from an electrical machine.

3. The intervention of a condenser in the induced circuit increases the intensity of the chemical action of the spark; but as the condenser diminishes at the same time the length and number of the discharges, it should be employed only when the ordinary spark is insufficient to produce the desired combination or decomposition.

4. A portion of the aqueous vapour decomposed by the discharge of the direct induction current undergoes electrical decomposition.

5. The quantity of gas or vapour combined or decomposed by the induction spark increases with the length of this spark, the intensity of the current remaining unchanged. In other words, the longer the spark with the same direct current, the more gas or vapour it combines or decomposes.

6. With a given induction apparatus, as well as induction current, there exists a length of spark corresponding to the maximum of chemical action.

The use of currents of gas or vapour offers great advantages in all processes relating to the chemical action of sparks. In this manner he has obtained as much as three litres of gas hourly by decomposing alcohol, ether, or acetic acid vapour. A current of carbonic acid, submitted to the action of an induction spark, gives a mixture of oxide of carbon and oxygen which in less than an hour increased in volume to 200 cubic centimetres. The decomposition of ammoniacal gas is still more energetic.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 6, 1861.

Dr. HOFMANN, President, in the Chair.

MR. A. W. LENNOX read a paper *On Bromide of Carbon*. This body, C_2Br_4 , heretofore obtained by the action of bromine upon alcohol or ether, was prepared by the author from olefant gas by a succession of alternate treatments with bromine and alcoholic solution of potash, precisely as chloride of carbon is usually prepared. It was deposited from its alcoholic solution in beautiful crystalline plates, having an aromatic odour. It fused at 50°C ., and sublimed at a higher temperature.

Dr. DAUBENY read a paper *On the Power Ascribed to the Roots of Plants of Rejecting Poisons or other Abnormal Substances Presented to them*. The author considered that the composition of the ash of any plant varied only within certain limits when grown in very different soils; although, indeed, a small variation in the relative proportions of potash and soda, and of lime and magnesia, might be found according as these ingredients were more or less abundantly supplied. But he contended that these variations had reference, not to the mineral matters associated essentially with the different tissues of the plants, but to the mineral matter of the fluids circulating through the vegetable organism. He inferred that the spongioles of the roots had residing in them a specific power of excluding those constituents of the soil which were abnormal and therefore inimical to the plant, but that they took up those which were normal in any proportion in which they chanced to present themselves, the redundant portions, however, left after the necessities of the organism had been provided for, being again excreted, so that a vegetable will only vary in mineral composition, in proportion to the relative amounts of the several proximate principles produced under the peculiar circumstances of its cultivation. He doubted whether poisons were ever taken up by the living roots of plants, although, when the vitality of the roots was destroyed by the action of a poison, some portion of it might enter the plant by physical imbibition. His experiments were made principally with barium and strontium salts, and with white arsenic.

THE PRESIDENT: I am sure we must all feel extremely obliged to Dr. Daubeny for the very elaborate paper in which he so lucidly treats a subject equally interesting on account of its purely scientific bearings, and on account of its importance for the purposes of agriculture. I see several gentlemen here who have paid particular attention to this question, and hope they will favour the meeting with any remarks which their experiments upon this subject may suggest.

Dr. GILBERT: There are one or two points to which I should like to refer. I quite agree with Dr. Daubeny that there is not, so far as facts would show, anything like a substitution of potash by soda in the way originally supposed. We find that there is a great difference in the composition of the ashes of vegetable substances, so long as they are green and unripe; and even within certain limits—but the limits are very distinct—we find a variation according to the condition of the soil; but the nearer we approach to the maturity of any one organ, the more distinctly is a definite composition visible. And this is even observable in comparing one professedly ripened product with another. For instance, we take wheat grain ripened in good seasons and in bad seasons, and we find in the ashes of that ripened in the bad season, a very much larger proportion of soda than in those of the grain ripened in the good season; and you will find in one season a very much larger quantity of starch, and in

another a very much larger proportion of nitrogenous substances, sometimes not in a perfectly ripe condition; and according to those circumstances we do find a certain variation. But the farther the organ has advanced towards finality, and the more matured it is, the more exact and permanent is the composition. I perfectly agree with Dr. Daubeny in the explanation which he gives of the occurrence of what may be called abnormal matters, at least, ex'aneous matters in professedly ripened substances; that is to say, it is to be accounted for by the fact that the substances are not really ripened and we have a large proportion of the proximate principles. This subject Mr. Lawes and myself went into considerably some time ago,—I think in 1847,—and we have also advocated this view in a paper before this Society. With regard to the question of the condition in which plants take up their food, I am disposed to think we really do not know very much about it, but at any rate it is not, I think, essential from the facts to conclude that they do not take it up absolutely in solution, but plants undoubtedly give off water during their growth. In relation to the substances which they fix we account for their taking up of almost insoluble substances; and what is more, I have seen plants grow to perfect ripeness in perfectly clear solutions, without ever having been in connection with any solid matter; so that at any rate they can grow and mature from solutions. With regard to the question of the taking up of poisons, I have observed that some of the evidence which Dr. Daubeny has quoted is already published in regard to that subject; but there are also some results of a gentleman, who is I believe a Fellow of this Society, also published in answer to those of Dr. Davy, in which he could not get any plants to grow which he manured with arsenical solutions. In the year 1843 we manured a large quantity of wheat with arsenical solutions, and a very large proportion of the plants died; but what did grow we very carefully took care of in the field, but unfortunately it was lost by other means; otherwise it was our intention to feed poultry with the grain, and observe the effect upon them, and also examine whether we got anything in the bones of the animal.

Dr. MARCET: Perhaps, Mr. President, you will allow me an observation upon this interesting paper, which I have listened to with very great attention and interest. From the many experiments which Dr. Daubeny has stated to-night, and among them those of Lindley, may it not be that the arsenic, used in Dr. Daubeny's inquiry, mixed with soil containing manure, and this soil being in a fit state for growing plants, enters into some peculiar chemical combination which neutralizes more or less its poisonous properties, at the same time enabling its rapid elimination from the plants growing on the soil in question; and that, in fact, the poison is not rejected by the roots, but absorbed and then excreted? If we consider the great analogy between vegetable and animal life, this elective property of roots will be difficult to conceive; for in animals every substance which the stomach and intestines contain in a state of solution, is absorbed within certain limits, regulated by the laws of endosmosis. On the other hand, we are acquainted with poisons which under certain chemical conditions lose much of their power; as, for example, mercury, a substance tolerated much better under some forms than under others; indeed, the virulence of a poison appears to be diminished if exhibited in a state which will effect its rapid elimination from the body. Such is probably, for instance, the iodide of mercury. These observations have only just occurred to me, and are offered with due regard to Dr. Daubeny's interesting views.

Dr. DAUBENY: I would remark, Mr. President, that Dr. Marcet's view would require that we should be able to detect poison in the plant. If we could find arsenic in the plant, then I admit the fact; but it appears to be very doubtful from my experiments whether the arsenic does

find its way into the interior of the plants. The few instances in which I have detected it, seem to be very well explained by the adherence of some small particles of the substance to the exterior; and therefore the inference I have drawn is, that it is not absorbed by the roots. The same remark applies to strontium, which is not poisonous to plants.

Dr. ODLING: A year or two ago, I was called upon to examine into the causes of the death of some cattle at Swansea. On examination, I found arsenic was the cause of death. The soil of the place on which they were fed was very rich in arsenic, and the animals had taken some of this arsenic into their bodies. The grass was also found to contain arsenic. I then sent for some turnips grown in the soil, but I could not detect any arsenic whatever in the tissues of the turnips. Then I had some of the soil which contained several grains of arsenic in the pound, and we grew some radishes in it, but we could not find any arsenic in them. The arsenic was in a very insoluble state. There seemed to be a great amount of copper slag; but I suppose the iron in a soil is quite sufficient to render any ordinary amount of arsenic insoluble in water. These results, then, seem to corroborate the results obtained by Dr. Daubeny. I read Dr. Davy's experiments at the time they appeared, and I thought them fallacious. There was no doubt about arsenic being present in this case, because there is a large quantity of pyrites in the shale. The shales which are in the coal mines in the district of Swansea, are very well adapted for growing potatoes. It is a well known fact that in Merthyr and Swansea they grow excellent potatoes.

The PRESIDENT: In the interest of the Chemical Society I hope that Dr. Daubeny will favour us with the result of the new researches which he proposes to undertake upon this important subject, as soon as they are completed.

The PRESIDENT then said, that there being no other paper before the Society that evening, he would beg leave to communicate verbally to the meeting some results he had lately obtained in studying the *Decomposition of Cyanurate of Ethyl*. Cyanate and cyanurate of ethyl, as is well known, when distilled with the hydrated alkalies are decomposed, carbonic acid and ethylamine being produced, thus,—

but if, instead of submitting the cyanate or cyanurate of ethyl suddenly to the action of the alkali, the two bodies be allowed to act gradually upon one another, the production of ethylamine is preceded by the formation of several intermediate bodies.

Dr. HOFMANN stated that when cyanate of ethyl is allowed to flow drop by drop into a retort containing ethylate of sodium, a powerful evolution of heat takes place, and a portion of the cyanate distils over; but the larger portion is converted into the cyanurate, which may be obtained by treating the mass left in the retort with hot water and crystallizing. If the mixture of ethylate of sodium and cyanurate of ethyl be heated, the temperature being gradually raised, a large quantity of ethylene gas is evolved, and an alkaline liquid distils over containing alcohol, an oily compound soluble in alcohol, difficultly soluble in water, ethylamine and a basic oil with a very high boiling point, which is partially decomposed by distillation. The basic oil forms with acids a series of salts, of which the iodide, the platinum- and gold-salts are the finest. The analysis of the two latter compounds gave the following formulæ:—

The free base, when liberated from its compounds, retains one equivalent of water, which it holds with considerable force, forming a hydrate of the formula,—

The action which takes place on distilling ethylate of sodium with cyanuric ether is very simple; the change is produced by the gradual action of the hydrate of sodium, which is formed by the decomposition of the ethylate, on the cyanurate of ethyl, thus,—

Dr. Hofmann pointed out that this base is the term in the ethyl-series corresponding to a body in the phenyl-series which he had produced some time ago by the action of tetrachloride of carbon on aniline. The phenylic compound may be referred either to two or to three molecules of ammonia, when it becomes cyantriphenylamine or carbtriphenyltriamine respectively, thus,—

In a similar manner the ethylated body also may be referred to two or to three molecules of ammonia.

The formulæ representing these bodies as triamines, indicate in some measure the manner in which the three molecules of ammonia are linked together in these compounds. They are also in accordance with the production of the phenyl term by the action of tetrachloride of carbon on aniline.

The base methyluramine, discovered by Dessaignes among the products of the oxidation of creatine, and guanidine, the substance lately obtained by Strecker by the action of oxidizing agents on guanidine,—belong to the same group of bodies. If these substances are referred to three molecules of ammonia, they can be expressed by the formulæ,—

The most perfect parallelism existing between the products of decomposition of these bodies clearly indicates their great analogy to one another.

Guanidine treated with nitric acid gives ammonia and urea

The ethylated base by distillation forms ethylamine and diethylurea

Habich and Limpricht have discovered that an indifferent body is produced when cyanurate of ethyl is treated with hydrate of potassium; this body obviously stands midway between the new base and cyanuric ether; the latter therefore passes through two stages before being transformed into ethylamine, the action consisting in the successive assimilation of water, the carbon of the cyanuric acid being gradually eliminated as carbonic anhydride.

Cyanuric acid, when transformed into carbonic anhydride and ammonia, must evidently undergo a precisely analogous series of changes, intermediate bodies being produced. These bodies are known, but have not as yet been obtained from cyanuric acid. A substance described by Wiedemann as *biuret* is one of these intermediate bodies, and *guanidine* is the other.

and by proper methods we may probably succeed in arresting the decomposition of cyanuric acid at the intermediate stages.

In conclusion, Dr. Hofmann pointed out that even now the cyanogen group is rich in examples of these gradual transformations. Liebig's researches on melamine have shown that this substance is converted by assimilation of water and separation of ammonia into ammeline, ammelide, and cyanuric acid, and as before stated, cyanuric acid may be transformed by assimilation of water and separation of carbonic anhydride, instead of ammonia, into biuret, guanidine, and ammonia.

The following equation shows the ultimate product of the action of alkalis upon melamine:—

But this assimilation of water takes place molecule after molecule, not less than five intermediate compounds being produced as is illustrated by the following symmetrical equations:—

Dr. WILLIAMSON: I may, perhaps, be permitted to draw attention to one circumstance connected with the starting point of Dr. Hofmann's remarks, I mean the reaction of hydrate of potash upon cyanic ether, which I think is not unimportant in this consideration of the transformation—I mean the question of what really happens—of whether it is a replacement of carbon for hydrogen or not. I must say that, in my own opinion the reaction, if you take in the whole process, cannot be represented as being an interchange of carbon and hydrogen. I think it is of necessity carbonic oxide, or the radicle that is combined in the carbonate, that interchanges with the hydrogen. Perhaps I may be permitted to show on the board what I mean. We will take as the starting point the formula of cyanic ether, which I will write as derived from the type of ammonia, in which one hydrogen is replaced by carbonic oxide, $C_2H_5CO N$. When we bring this in contact with hydrate of potash, we must take, in order to represent the reaction, at least two atoms of hydrate of potash,

and we have then an interchange of carbon and oxygen from the one group with hydrogen from the other. I will write it out in the form of an equation so that there may be no doubt. In this reaction there can be no possible doubt that what takes place is an interchange of hydrogen and carbonic oxide. Now, a partial decompo-

sition of the same kind takes place in the formation of the remarkable body mentioned by the President, $(C_2H_5)_3H_4CON_3$. I say the same interchange takes place, and that precisely the same formula must be used, if you take into account the two products formed. I will write the formula of cyanuric ether. Twice this quantity of hydrate of potash, in four atoms, and replace the H_4 in them by two atoms of carbonic oxide, and get two atoms of carbonate of potash,

and the H_4 by taking the place of $(CO)_2$ in the cyanuric ether give rise to the body $(C_2H_5)_3COH_4N_3(C_2H_5)_3N_3CO$.

The President: I am much obliged to Dr. Williamson for his remarks, and may state at once that I have no objection whatever to his views regarding the action of the caustic alkalies upon the cyanic ethers. I have only one observation to make. The new bases which I have described contain their oxygen in the form of water, which is separated when they are converted into saline compounds. These saline compounds contain no oxygen. Moreover, several of the bases, e.g., the carbotriphenyl-triamine,

are known in the anhydrous condition. Whatever may be the reaction by which the formation of these bodies is accomplished, it is impossible to assume carbonic oxide either in the anhydrous bases or in their saline compounds. Probably the rapid sketch which I have endeavoured to delineate of these new bases did not set forth, in a sufficiently forcible manner, the anhydrous condition of their saline compounds. One more remark regarding the substitution of carbon for hydrogen. I do not wish in any way to press this view in an undue manner. I have already pointed out that these substances may be represented as cyanogen compounds. There are, in fact, some points which favour this mode of viewing them. Melaniline is formed by the action of chloride of cyanogen upon aniline, and may, therefore, with perfect propriety, be considered as diphenylcyanidamine.

There are at present no data at our disposal by which this question could be settled either way.

Dr. WILLIAMSON: My remark was only with reference to the body you described yourself, Sir, as containing oxygen. Of course, I did not allude to the product of decomposition from which oxygen is removed as water. I know no other view of the formation of the interesting body you have mentioned to us than that which represents it as effected by the interchange of carbonic oxide for hydrogen.

The President: I repeat, I have no objection to the view which you take regarding the form of the decomposition, but cannot accept your view of the constitution of the bases themselves.

Dr. ODLING: I understand you to say, Dr. Hofmann, that by simply acting upon the body which Dr. Williamson has written, the hydrochloric acid turns out the water, and that by the addition of a hydrate you would there get back the original body. They thus differ from one another, as chloride of potassium differs from hydrate of potash.

The President: They do.

NOTICES OF BOOKS.

Report on the Presence of Bisulphide of Carbon in Gas, addressed to Robert Jones, Esq., Engineer to the Commercial Gas Company. By FRED. VERSMANN, F.C.S. London: 1861.

In the early part of last year the battle of the Metro-

politan Gas Regulation Bill was being fought in a committee-room of the House of Commons. Among the points then hotly contested—so hotly, indeed, that the barristers engaged for the Companies withdrew from the field, and left the agents to fight out the case by themselves—was the quantity of sulphur which was usually present, or which might be allowed to be present in gas, without detriment to the consumers or disadvantage to the Companies.

It was about the same time that the Commercial Gas Company employed Mr. Versmann to make some determination of the amount of sulphur in their gas. That gentleman accordingly made a series of experiments at the *Works of the Company*, and the results which he obtained, together with the inferences he drew and the speculations he indulged in, are contained in the Report now under review. But before we refer more particularly to this Report, it will be as well to notice briefly what had previously been said on the subject.

Sulphur is admitted on all hands to be a most pernicious ingredient in gas. It is also conceded that it is possible to make gas which shall contain a very small amount in the form of bisulphide of carbon, while it has been found perfectly easy to remove every trace of that which existed as sulphuretted hydrogen.

The amount of sulphur in gas has been variously estimated by different experimenters. Mr. Lewis Thompson, who was considered a great authority on gas chemistry, has said that the amount of vapour of bisulphide of carbon in gas is seldom less than $\frac{1}{1000}$ th of its bulk, which will correspond to about 119 grains of sulphur in 100 cubic feet. No other chemist has ever, that we are aware of, found so large an amount as this; but it seems probable that other estimates may have been as much below as Mr. Thompson's might have been above the actual amount.

On the part of the companies it has been sometimes said that sulphur in gas is a "myth," and the damage done by it a delusion. Of the mischievous results, however, there can be no doubt. One of the first things which drew public attention to the matter was the damage done to the books in the library of the Athenæum Club. Many of our readers will, doubtless, remember the discussion on the subject, in which the most celebrated English chemists of the day were engaged. Their investigations left no doubt that the injury done to the binding of the books was owing to sulphuric acid formed by the oxidation of the sulphurous acid generated in the combustion of the gas. Other libraries have since suffered to an equal degree, as our readers may see by referring to Dr. Letheby's Report, "On the Coal-Gas Supplied to the City of London, 1854," and beyond this there is not a silversmith, hardware-dealer, or draper, whose shop is lighted with gas, but has his own tale of the damage done to his goods by sulphurous vapours. Mr. J. E. Clift, the proprietor of the Redditch Gas Works, indeed, told the Committee of the House of Commons, that it was found impossible to use gas containing sulphur in some departments of the needle factories, so injurious was it found to be. It was natural then that an Act of Parliament, professedly designed to regulate the quality of gas, should fix on some limit which the quantity of sulphur was not to exceed. Dr. Letheby in his evidence, we believe, said, that the largest quantity he had ever found was 20 grains in a 100 cubic feet, and this was the limit fixed upon. But at one of the last sittings of the Committee (July 18) Mr. Baxter on behalf of the Companies, of whom, we presume, the Commercial was one, said that gas engineers admitted that if the "twenty grains were made forty it would do." The Directors of the Commercial Company, we may suppose, had Mr. Versmann's Report in their hands at this time, and we may now quote his results:—

Series of Experiments made at the Works of the Commercial Gas Company.

Commencement of Experiment.	Cubic feet of gas burnt.	Grains of BaO ₈ O ₃ obtained.	Grains of sulphur in 100 cub. ft. of gas.	Mean of grs. of S. in 100 cub. ft. of gas.
1860, Feb. 7	13	3'08	3'23	2'99
" 28	30	6'80	3'12	
March 5	75	14'41	2'64	
" 14	118	25'42	2'96	6'35
May, 17	3'5	1'53	6'00	
" 21	2'0	0'98	6'70	

Now, we do not intend to question for one moment the perfect accuracy of the above results; but, coupling them with the fact above mentioned, they could not but excite astonishment in the mind of the most innocent person. Was it possible that the Companies knew much better than chemists how much sulphur their gas contained; or were they, when many complained of the badness of their gas, coolly asking permission to make it a great deal worse? Thinking that an independent examination might help us to a solution of these questions, and having the gas of the Commercial Company as supplied to their customers at command, we decided on making a series of determinations for ourselves. Our readers will see that our experiments were made at a distance of twelve months from those of Mr. Versmann; but as his report was written in June, 1860, and only issued this year, the inference is that the Directors wish it to be supposed that the gas Mr. Versmann examined is the gas they ordinarily supply.

The results of our experiments were as follows:—

Commencement of Experiment.	Cubic feet of gas burnt.	Grains of BaO ₈ O ₃ obtained.	Grains of sulphur in 100 cub. ft. of gas.	Mean of grs. of S. in 100 cub. ft. of gas.
1861, April 5	25	108'7	59'56	57'38
" 7	25	113'8	62'34	
" 9	25	89'5	49'03	
" 12	25	115'1	63'07	
" 22	25	109'4	59'95	
" 25	25	91'9	50'36	

Our readers will probably share the astonishment we ourselves felt at the enormous discrepancy between our own results and those of Mr. Versmann. Well might the companies have asked for forty grains! Sixty, indeed, would hardly have been too much for them! That there might, however, be no mistake about the matter, we instituted another series of experiments, the results of which we condense.

Cubic feet of gas burnt.	Grains of BaO ₈ O ₃ found.	Grains of Sulphur in 100 Cubic Feet.		
		Minimum.	Maximum.	Average.
175	793'3	39'9	59'95	49'37

For reconciling the discrepancy between the results we obtained and those obtained by the Author of this Report, various hypotheses suggest themselves; but as our readers are probably as ingenious in guessing as ourselves, we need not further occupy our space with the matter.

Passing from Mr. Versmann's results to his inferences and speculations, we feel bound to characterise them at once as an elaborate mystification. "In proceeding," he says at starting, "to the practical view of the question, i.e., whether this amount of sulphur" [i.e., the amount which he obtained] "may possibly become in any way injurious or obnoxious to persons inhaling the atmosphere of places where the gas is burnt, we must enter the dry field of calculation." Now, no one of credit—so far as we are aware—ever said that the sulphur was injurious to persons inhaling the atmosphere of places where gas is burnt. What has been said, and what has been proved over and over again, is that the sulphur products are injurious

to metal work, to the delicate colours of various textile manufactures, to the binding of books, and to many other things. On the other hand, it has been said that the healthiness of London partly depends upon the disinfecting agency of the sulphurous acid in the atmosphere, no little of which is derived from the gas.

To show, however, that the sulphurous acid cannot possibly injure people, the Author goes on to calculate from his results what proportion by weight of sulphur is contained in a given weight of gas, and how much by weight and volume of sulphurous acid is formed by the combustion of a given quantity of the gas; and then proceeds to show that the burning of seven lucifer matches would give as much sulphurous acid as the combustion of 100 cubic feet of the worst gas he examined. We may dismiss this part of the subject with the remark, that our experiments show, that to arrive at an ordinarily correct result, Mr. Versmann's sulphur calculations must be multiplied by eight at least, and his lucifer matches be made fifty-six, the combustion of which in a room would indubitably give a suffocating odour to the atmosphere.

We need not follow the Author into his carbonic acid calculations, made with the view of showing the far greater danger to animal life from the amount this body formed during the combustion of the gas than from the sulphurous acid generated from the quantity of sulphur he found. *Cela va sans dire*, as our neighbours say. We may, however, express a qualified agreement with Mr. Versmann when he says: "I am of opinion, that before any person could be inconvenienced by these quantities of sulphurous acid, he must have ceased to live, long previously, from the effect of the carbonic acid." After that event we do not imagine the sulphurous acid in this world would inconvenience him at all; but it is easy to see what Mr. Versmann means if we put *would* for *must* in the foregoing sentence.

We have said enough to show the urgent necessity for the appointment of a Gas Examiner at the East end of the Metropolis, and now return for a moment to the Commercial Company. The Directors have just issued a circular to their customers, announcing that they have made arrangements for improving the quality of their gas to the standard of the Act of Parliament, and consequently intend to raise the price. How perfectly gratuitous! The Act allows 20 grains of sulphur in 100 cubic feet; and they publish a Report to show that the maximum amount contained in their gas is 6'7 grains, and then talk of improving the quality to the standard of the Act. Whether they do improve it or not, however, our readers will shortly learn.

There remains something to be said about the methods of estimating sulphur in gas, and the removal of bisulphide of carbon, to which we intend to recur in our next number.

NOTICES OF PATENTS.

Purification of Gas. F. J. EVANS and G. F. EVANS. (Not proceeded with.)

THE patentees propose to eliminate the sulphur compounds by admitting to the foul gas a small proportion of atmospheric air, or pure oxygen, and then passing the mixed gases over one of the following materials, heated to any temperature between 200 and 400 degrees Fahrenheit:—Coke, charcoal, asbestos, chalk, and asbestos coated with spongy platinum may be used for the purpose, and the heated purifier containing one of these substances is placed intermediate between the condenser and the ordinary purifier. The sulphur compounds become oxidised, and the sulphurous acid produced may be removed either by passing the gas through the crude ammoniacal liquor, or by adopting any of the ordinary processes of purification.

The problem involved in the foregoing specification seems to have been met by the suggestion, recently patented, of applying the hydrate of lime to effect the same purpose. When heated to the temperature indicated slaked lime appears to possess the property of converting all the sulphur compounds present in the impure gas into sulphuretted hydrogen, or such products at least as are capable of being removed subsequently by the ordinary lime purifiers. This method does not, moreover, render necessary the admixture of air, a proceeding which, if possible, it is certainly desirable to avoid.

Electric Telegraph Cables or Ropes. C. S. DUNCAN.

For the purpose of insulating the conducting wire or wires they are bound in a spiral manner with strips of cane which have been well tanned with oak bark, terra Japonica, or any known tanning agent. Raw silk may be used for binding on the strips of cane. The covered wire is then thinly coated with gutta-percha, india-rubber, or marine glue, or any mixture of these, and the interstices between the coils well filled up. This system of proceeding is repeated as often as desirable for the purpose of imparting strength to the wire, or of preserving it from external injury, and the admission of water. The cable thus built up is further covered with hemp, yarn, or wood shavings, and finally bound with strands of copper or other metallic wire, wire-rope, or rope composed simply of hemp.

Preserving Electric Telegraph Cables and Wires prior to their being laid. R. A. GLASS. (Not proceeded with.)

The invention of Mr. Glass consists in packing the cables in air-tight boxes, or cases with double sides throughout, into the outer spaces of which may be introduced water, ice, or any cooling mixture. Or, further, the cables may themselves be immersed in water, and the tanks, which are now to be single cased, closed with tight covers, and the whole packed in a material being a non-conductor of heat.

Protecting and Insulating Subterranean Telegraph Wires. A. F. JALOUEREAU.

This patent refers to a process of insulating metallic wires by enclosing them within bitumenized paper tubes, or similar tubes made of any non-conducting material.

Purifying Oils and Varnishes. N. C. SZRELMLEY.

This specification refers to a mode of treatment for the clarifying of oils and varnishes by processes of filtration through certain porous media. In some cases the viscid character of the oil or varnish requires to be overcome by slightly warming prior to passing through the filter. This last recommendation might, in the case of some oils, sensibly depreciate their quality by rendering them more liable afterwards to become rancid; but this objection cannot possibly apply to varnishes which are themselves prepared at temperatures more elevated than that at which the process of filtration is intended to be conducted.

A New Mode of Obtaining an Article resembling Honey. C. STEVENS. (A Communication.)

This invention consists in the production of a saccharine compound bearing a certain resemblance to honey, by the action of diastase upon any one of the ordinary varieties of starch. Whether derived from wheat, rice, or potato, the starch is mixed with about three times its weight of water, and a very small proportion of sprouted barley or infusion of malt then added. This latter ingredient acts the part of a ferment, and, at temperatures somewhat below 200 degrees Fahrenheit, induces the conversion of

the starch into grape sugar, or more commonly into a mixture of dextrin and sugar. Such a product would undoubtedly possess a sweet flavour, but could scarcely, we think, be mistaken for ordinary honey.

An Improved Fuel. C. L. HANCOCK. (Not proceeded with.)

THE inventor suggests the binding together of small coal or coal-dust with the help of water and lime as a cement. The mass resulting from the incorporation of these materials is to be formed into cakes or blocks, and dried either in the air or by exposure to a moderate degree of artificial heat. No great pressure is required in the formation of these blocks; and, although slaked lime is preferred by the inventor, he claims also the use of "compounds containing lime" (under which term are probably comprehended hydraulic limes, mortars, cements, &c.), for the purpose of agglutinating the coal particles, and of setting them into shaped masses.

As compared with any of the ordinary kinds of "patent fuel," the advantage of the improved mode of manufacture pointed out in the foregoing specification would appear to be very problematical. One of the first considerations taken into account in the selection of a fuel for all ordinary purposes is its comparative freedom from mineral impurities; for not only do these tend to impede the combustion of the fuel, but directly contribute to increase the proportion of ash left on burning. Small coal is often objected to, on account of its containing considerably more mineral matter than larger blocks from the same sample; and when it is proposed still further to add to the proportion of an objectionable ingredient, we might safely venture to predict the result of such a suggestion.

CORRESPONDENCE.

The Monohydrate of Sulphuric Acid.
To the Editor of the CHEMICAL NEWS.

SIR,—You did me the honour to report a verbal notice which I made to the Royal Society of Edinburgh of an experiment on sulphuric acid. It was stated, as the result of four experiments, made some years since, that the true monohydrate could be obtained by keeping it at a temperature about 50° below its boiling point. I have repeated these experiments lately, but cannot obtain the same result, the acid always being at least half a per cent. too weak, and the specific gravity too low. It is better promptly to confess an error than to allow it to occupy another chemist's time in attempts at verification. I am at present engaged in endeavouring to find out how I was deceived in my experiments.—I am, &c.

LYON PLAYFAIR.

Edinburgh, July 8.

The Sale of Poisons.
To the Editor of the CHEMICAL NEWS.

SIR,—I quite agree with your Correspondent, that no person should commence the business of chemist and druggist who has not obtained a certificate of competency. This should be the case in England; but how much greater a necessity there is for such a law in Ireland it is difficult to say. I was once in a small town in the North of Ireland, some distance from home. In the course of the day I had a violent griping pain, and naturally applied for something to allay it to the druggist of the town. I found that he carried on two rather dissimilar trades, for he was a druggist and a publican. In the front room of the house medicine was dispensed, in the back room whisky. On stating the purpose of my visit, the chemico-publican

weighed out some muriate of morphia on a dirty, and, I should imagine, not very accurate pair of scales. He then went to the other part of the establishment, and brought therefrom a tumbler, from which someone had just been drinking porter. In this my medicine was mixed. I ask anyone if it is right that such men should be allowed to dispense medicines.—I am, &c. G. F. R.

Chemical Notices from Foreign Sources.

ORGANIC CHEMISTRY.

Preparation of Caramel and Assamar.—Peligot's way of making pure caramel is to heat the sugar between 215° and 220° C. as long as aqueous vapour is evolved, treat the residue with water, filter, and then precipitate the caramel from the aqueous solution by means of alcohol. It is difficult, however, to wash this precipitate free from the mother liquor, and Dr. J. J. Pohl has found it easier to make caramel in the following way (*Sitzungsber. d. Akad. d. Wissenschaft zu Wien*, Bd. xli. s. 623): He heats cane sugar contained in a metallic vessel which will hold 10 or 15 times the volume of the sugar in an oil bath to 210° or 215° C. as long as aqueous vapours escape, stirring up the mass occasionally with a spatula. The mass is afterwards finely powdered and digested with alcohol for two or three hours, and the digestion is repeated until the fluid no longer tastes bitter. The residue contains, besides the caramel, another body greatly resembling Voelckel's Caramelan. If the heat be continued sufficiently long, the alcoholic solution has an intensely bitter taste, and on evaporation yields a brown mass possessing all the properties of Assamar. This body, it seems, retains its properties in alcoholic solution, but in dilute aqueous solution is slowly changed into sugar again—grape sugar, however, not cane.

ANALYTICAL CHEMISTRY.

Estimation of Oxygen in Organic Matters.—Stromeyer describes (*Annal. der Chem. und Pharm.*, Bd. cxvii. s. 247.) a method of estimating oxygen by a combustion. He employs the oxide of copper which is made by heating gently the carbonate $2\text{CuO}, \text{CO}_2 + \text{HO}$. One part of the substance to be analysed is mixed with four parts of this oxide of copper and two parts carbonate of soda, and placed in a combustion tube with about as much granulated oxide of copper before it. (The oxide of copper is granulated by making it into a dough with one-tenth of carbonate of soda and water, and then pressing it through a sieve.) After the combustion the oxide of copper is dissolved in a solution of persulphate of iron containing free sulphuric acid. The solution is moderately diluted, and then the amount of oxygen given up by the organic matter burnt is determined by a standard solution of mineral chameleon. The author gives a great number of experiments showing the results obtained by his process. The amount of oxygen is in general too small, but the loss never exceeded a quarter of an atom.

TECHNICAL CHEMISTRY.

Herring Pickle.—Messrs. Girardin and Marchand (*Journal de Pharm.*) describe the employment of herring pickle as a manure in agriculture. After describing the process of curing herrings on the north and west coasts of France, they thus describe the liquid in question:—

Herring pickle is a reddish liquid, rendered turbid by various organic matters, as blood, oil, &c., but when filtered it has a deep amber colour. Our authors have, during the past five years, made several analyses of the crude pickle as used for manuring land, and having a density varying from 20° to 25° Beaumé. The following is the mean of several analyses of a litre (1000 gramme measures) of pickle:—

Chloride of sodium	255.11 grammes.
Sulphate of soda	5.73 "
Phosphate of lime	0.98 "
Ammonio-magnesian phosphate, traces.	
Phosphate of ammonia	1.92 "
Phosphate of propylamine	3.53 "
Lactate of ammonia	5.76 "
Lactate of propylamine	10.79 "
Albumen	1.90 "
Soluble organic matter	15.10 "
Insoluble organic matter.	17.36 "

318.18

Propylamine ($\text{C}_3\text{H}_7\text{N}$), or its isomer trimethylamine, exists normally in herring pickle. Its presence was first stated by M. Wertheim, and we have confirmed his researches. In an experiment on a larger scale we find that 100 parts of the dry matter obtained by neutralising with chlorohydric acid, the volatile alkalies which are disengaged from it under the influence of potassa or lime consist of

Chlorohydrate of ammonia	30.23 parts.
Chlorohydrate of propylamine	69.77 "

We find the aqueous solution of propylamine to possess the following properties:—It is very alkaline, and exhales a strong ammoniacal odour, recalling that of herring pickle. It precipitates the salts of alumina, but an excess dissolves the precipitate. It yields with the salts of copper a liquid of sky-blue colour. Neutralized with chlorohydric acid and properly evaporated, it yields very deliquescent crystals, soluble in absolute alcohol when they are perfectly dry. Chlorohydrate of propylamine combines with chloride of platinum and forms a double salt, which can be isolated in transparent octahedral crystals of a beautiful orange red colour, and preserving a persistent odour of herring pickle. Finally, sulphate of propylamine and sulphate of alumina unite to form an alum like ammoniacal alum, but which is deliquescent.

In the recent pickle, the authors found creatin, inositol, and a body analogous to glucose, whilst in the old and fermented pickle butyric acid was a constituent.

MISCELLANEOUS.

Chemistry of the Comet.—Since the article in the last Number was written, I have been able to get a somewhat more satisfactory observation of the spectrum of the light emitted from this body. The light was concentrated by passing through a compound lens, of large aperture and short focus, before receiving it on to the slit of the spectroscope. A coloured spectrum was distinctly though faintly visible, extending from the red to the blue, the latter colour, however, being very faint, and no violet being distinguishable. The general appearance of the spectrum was similar to an excessively weak solar spectrum. The lines D, E, δ , and, I fancy, F, were visible; in addition to which there was a suspicion of a faint band in the upper part of the green, but whether this was due to lines or other cause I am unable to say. No bright lines could be seen. The light is, therefore, principally of solar origin; the proper light of the comet, if it have any, being very faint in comparison. The above observations refer only to the light from the nucleus and that part of the coma immediately surrounding it.—W. CROOKES.

Gold-Producing Machinery.—A Return recently laid before the Parliament at Melbourne, by the Minister of Mines, shows the rapid progress made to the 31st of December last, in applying steam and machinery to the production of gold in that colony. It shows that on

December 31, 1860, there were 107,572 adult miners—viz., 60,874 Europeans and 28,100 Chinese engaged in alluvial workings, and 18,570 Europeans and 28 Chinese engaged in quartz-mining. The number of steam-engines employed in alluvial workings for winding, pumping, puddling, &c., was 294, amounting to 4137 horse-power. Besides steam-engines there were 3957 horse-puddling machines, 354 horse whims, 128 water-wheels, 56 horse-pumps. In addition to these there were engaged in quartz-mining and crushing 420 steam-engines, equal to 6696 horse-power, 158 whims, 6 water-wheels, 26 whips, and 40 horse-crushing machines. The approximate value of all this mining plant is set down at 1,259,660*l.* and there are in the principal towns in the mining districts manufacturing of engines and machinery that compete successfully with those imported from England. Great as is the progress shown by these figures in giving a character of permanency to the supply of gold, it is now probable that the colony is about to enter on a still greater development of this source of wealth, the alluvial diggers having hitherto been kept idle for a large portion of the year by the want of water. Government are forming large reservoirs for collecting and storing rain on the various diggings, and quartz-mining is likely to receive an immense impetus from the many experiments being made and patents claimed for improved methods of extracting the finer particles of gold from the *débris*, or tailings of quartz that have passed through the ordinary processes of crushing, washing, and amalgamating. Among those thus employed is Mr. Porter, of Italian Gully, near Ballarat, who being engaged in quartz-crushing, announces that he has discovered that by placing 76*lb.* of quicksilver in the bottom of a retort, and then putting into it 23*lb.* of tailings, and placing the retort on the furnace until the quicksilver is vaporized, it is by this means brought into contact with all, even the most minute particles, while the loss of quicksilver has been only 6*oz.* out of the 76*lb.* placed in the retort. The result alleged to have been obtained in these comparatively small experiments is, it is remarked, "so great that, if the same can be obtained on tons as is announced on cwt., it will be difficult to give an approximate estimate of the extent to which the production of gold will be carried in Victoria; for the great bulk of the colony, from Ballarat to Twofold Bay, and from the banks of the Murray and Owens Rivers to the parallel of Melbourne, is one great goldfield of more or less richness." The immediate consequence at present is that quicksilver is all bought up at 2*s.* 1*d.* to 2*s.* 6*d.*, and is now held for 3*s.* to 3*s.* 6*d.*

Hot Water as an Agent in Warfare.—Some years ago, the employment of hot water and steam as a means of defence made incidentally and without special appliances, was signally effective. A small British war steamer, cruising in the China seas, was attacked by a whole fleet of the pirates who infest those waters in such great numbers, and, notwithstanding the best defence that could be made with guns and small arms, they were commencing to board in swarms, when the engineer, without orders, brought out a hose from the boiler to the deck, and by a little well directed squirting, in a very few seconds drove them all overboard into their boats or into the sea, and many who escaped scalding were drowned.

Minerals in Siam.—Mr. H. J. Moyle, of Bake, in Cornwall, who has been travelling in South Africa, was attracted to Siam by its novelty and the facility of exploration disclosed by the recent treaty. Having made his way to Nophburi, about sixty miles in a direct line from Bangkok, he found the country so rich in copper and iron ores (of the former of which the natives made no use, being ignorant of their commercial value) that he returned to Bangkok, and obtained, under a deed from the Siamese Government, permission to work the lodes of that district, on payment of a royalty of ten per cent. of the ores extracted. It must, however, be remembered that the Siamese

Government is under no treaty obligation to permit foreigners to work the mines of Siam. The country along the banks of the River Chan Phya (Meinam), as far as Nophburi and its environs, lat. 15 deg. 25 min., is covered with alluvial deposits, or a mixture of these and diluvium. The hilly and mountainous districts, extending north and south in this latitude, and running many hundreds of miles in both directions, contain many valuable and rich mineral productions, though the natives do not avail themselves of them by working mines. In these hills I detected several rich and valuable veins of copper ore, principally in grauwacke; I considered them of so much value and importance, that I applied for and obtained permission from the Siamese Government to work them for five years, on payment of a royalty of one-tenth of the ores to the Crown of Siam. Lead and silver ores I also discovered, as well as enormous beds of magnetic iron ore and specular iron ore. The country to the north is carboniferous limestone with positive indications of the existence of coal. The rivers, creeks, and canals, with which this country abounds, extending in many places to the base of the hills, afford great facilities for transport, &c. I am impressed with the opinion that, should a fair portion of encouragement be given, the country of Siam will rival, if not surpass, any country of the East in the richness of its mineral productions.

Telegraphic Extension.—Steps are being taken for carrying out the new system of telegraphic extension in the metropolis and provinces on the principle of a fixed annual rental to public and private establishments, so as to furnish them with an exclusive wire for their own use and private means, hitherto unattainable by the ordinary telegraphs, for the receipt and transmission of intelligence. The wires will be combined into ropes 230 yards in length, containing 40, 80, or 100 wires, according to the requirements of the district; and in connecting different districts a system of triangulation is to be adopted, dividing the environs and towns into a series of triangles, as nearly equilateral as possible, with sides about a mile in length. The supporting posts will be fixed at intervals of 200 yards on the tops of the houses, and it is anticipated that the net-work of wires will, when extended over the metropolis, act as a "lightning" conductor, and remove all danger to be apprehended from lightning.—*Mechanics' Magazine.*

ANSWERS TO CORRESPONDENTS.

* In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

* All Editorial Communications are to be addressed to the Editor, and Advertisements and Business Communications to the Publisher, at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

Carbon.—The process is not yet published: we will give it as soon as possible.

A Constant Reader will find his query answered in the leader of our last Number.

W. P.—We will make inquiries and communicate the result in a subsequent Number.

J. Barclay.—The subject is now under consideration. We hope shortly to be able to give a series of such articles.

Binitronaphthalin.—**W. E. R.**—This compound is prepared by acting on naphthalin with strong nitric acid, at a slightly elevated temperature.

W. Gilkes.—We are unable to explain "why the blood does not coagulate in the body of a person killed by lightning." Is it certain that such is the case?

J. J.—The water thrown on to the recent great fire could not have been decomposed by the heat alone. Water requires a temperature approaching that of melting platinum to decompose it, and in our observations on this fire we could not see any parts, even where it was raging most fiercely, where the temperature was as high as a white heat. In only a few instances it reached a yellow heat.

THE CHEMICAL NEWS.

VOL. IV. No. 85.—July 20, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Analysis of Mineral Waters, and on the Arrangement of the Results, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

PERHAPS I may be allowed to make a few general observations on the analysis of mineral waters, the popular notions regarding which I have found to be very undefined, if not incorrect. The resources of chemistry are sometimes overrated and sometimes underrated, and in both cases the effect is to discredit its professors,—in the one because the results fall short of expectation; in the other because facts which can really be proved beyond dispute may seem to be beyond the power of the chemist to demonstrate, and are hence viewed with suspicion as being hypothetical, when they are not so.

In the analysis of by far the greater number of compound substances, certain preliminary operations, partly mechanical and partly chemical, are requisite, in order to bring the materials into solution, in which state only can the several acids, bases, metals, and so on, be removed from their combinations by the re-agents employed. But in the case of water, everything is already in solution, and it might be supposed therefore that the analysis must be a matter of comparative simplicity. Such, however, is not the fact; on the contrary, the very solubility of all the constituents deprives the analyst of one of the most ready and accurate means of separating them from each other. But there is another reason why the analysis is of a complex description, viz., the great variety of acids and bases simultaneously present. Each of the bases is, of course, capable of combining with any one of the acids; and as most waters are neutral to test paper, it follows that all, of both acids and bases, must be in some state of combination. The ultimate object of the inquiry is to discover what compounds—what salts, in fact—are present in the water; and we are led to endeavour to separate them directly from each other. Now, the ordinary method of separating salts which may be in solution together is by evaporation and crystallisation; by taking advantage of the various solubility of different salts at certain temperatures, some are made to crystallise out from the hot solution, some as it cools, and others by gradual and spontaneous evaporation; and in this way, by a continuation of the process, the salts are finally obtained distinct. Such a process is applied, on a manufacturing scale, in the treatment of sea and brine spring-waters, &c.

But this method, besides being inconveniently operose and tedious, is far too rough and uncertain in its results to deserve the name of analysis. A modification, however, of this method was adopted in the earlier attempts at analysis, and promised to lead to more correct results

with less loss of time. The water was first of all evaporated to dryness, and the saline mass weighed. The constituent salts and other ingredients were then separated, one after the other, by the use of various solvents, which had the property each of dissolving some one or two only of these constituents. Thus alcohol dissolved out the alkaline and earthy chlorides; then cold water, or a solution of sulphate of lime, dissolved sulphates of soda, potassa, and magnesia; then weak acid dissolved carbonates of lime and magnesia, hot nitric or muriatic acid dissolved sulphate of lime and oxide of iron, and silica remained to the last undissolved. The bases in each little group could then be separated without difficulty by the usual means. A method of this kind will be found described in some of the earlier editions of Brande's Chemistry, and in similar works.

This method is faulty for two reasons. In the first place, the solvents used are not altogether without action upon the constituents, which they are presumed to leave behind, so that the several solutions are found to contain small quantities of the latter. Accuracy, therefore, is impossible. The other reason is not so self-evident, but it is even more weighty. It is, that there is no certainty that the salts thus obtained really existed in the water. The acids and bases contained in these salts were of course there; but that they were combined each to each, in the manner represented by the salts obtained by evaporation, there is no evidence whatever to show. If we take the same acids and bases in a free state, cause them severally to combine in various ways to neutral salts, and then mix the solutions of these salts together, we shall, on evaporating the solution, always obtain a saline mass of similar composition, however various may have been the forms of combination into which we had at first thrown the acids and bases. Thus, let A, B, C, be three acids, and α , β , γ , three bases; suppose that on evaporating a solution which contains them in certain proportions the following salts have been obtained α A, β B, and γ C. It is clear that this is not the only way in which these constituents may be combined. No less than five other combinations are possible, thus:—

I.	II.	III.	IV.	V.	VI.
α A	α A	α B	α B	α C	α C
β B	β C	β A	β C	β A	β B
γ C	γ B	γ C	γ A	γ B	γ A

And if the three salts formed by any one of those groups be separately dissolved, the solutions mixed, and the liquid evaporated, the residue will in all cases contain only the three salts first mentioned, viz., α A, β B, and γ C. These salts are deposited in succession as the evaporation goes on, and it will be found on investigation that those which are first deposited are invariably the least soluble of all (in the case supposed,

¹ It will be observed that in this table each binary compound occurs twice. The total number of binary compounds possible is consequently nine.

the nine) forms of combination which can be obtained from the acids and bases.

There is thus strong presumptive evidence that the arrangement of acids and bases which prevail in the dry salts is, so to speak, accidental, and that, whatever may be the combinations in the solutions, the salts may be, in fact, only formed at the instant of their deposition, under the influence of cohesive force, which is so well known to modify the mere chemical elective affinity. The phenomenon is, in fact, identical with the ordinary one of precipitation, and depends on the same causes.

The inquiry leads us back to doctrines which lie at the very threshold of chemical science—those of affinity and combination. In the last century, when chemistry was but in its infancy, Berthollet, a most accurate observer, came to the conclusion that union and decomposition were not wholly determined by affinity, but that the relative quantities of the several bodies in presence of each other influenced the nature of the compounds which they might form, thus controverting the older views of Bergmann. But the promulgation by Dalton, in the early part of the present century, of the Atomic theory, and by Berzelius of his electrochemical theory, tended entirely to discredit the doctrines of Berthollet and his school. More recently multiplied research has turned the current slowly, but decidedly, in the opposite direction. The portion of Berthollet's theory which held that the relative proportions of the constituents in a compound might vary, has, of course, been permanently exploded. Compounds when formed must have a certain never-varying composition; but the question of the sufficiency of mere elective affinity to determine what compounds shall, in certain cases, be produced, has met with a different fate. Every day's experience brings proofs that, however true the electrochemical theory may be in a general way, there are a host of phenomena for which it fails by itself to account; temperature, state of aggregation, degree of solubility, and, what we are now chiefly concerned in, quantity—all modify the results in a way different from that which the mere relations of affinity would lead us to anticipate. Still, however, the question before us remains unanswered—What is the actual state of combination of acids and bases, so long as the solution is too dilute to afford a crystalline precipitate under the influence of cohesion, which, at a certain point, subverts the chemical affinities? It is evident that the ordinary methods of chemical inquiry are at fault, and a decision, if arrived at at all, must be founded on other considerations. The following quotation from the last edition of Turner's Chemistry shows one kind of argument employed. After speaking of a supposed mineral water containing sulphuric and hydrochloric acids, and lime and soda, in which case, of course, sulphate of lime and chloride of sodium will be obtained on evaporation, he continues:—"The late Dr. Murray, who treated this question with much sagacity, observes that some mineral waters, which contain the four principles above mentioned, possess higher medicinal virtues than can be ascribed to the presence of sulphate of lime. He advances the opinion that alkaline bases are united in mineral waters with those acids with which they form the most soluble compounds; and that the insoluble salts, obtained by evaporation, are merely products (as distinguished from educts). He therefore proposes to arrange the substances, determined by analysis, according to this supposition. To this practice there is no objection; but it is probable that each acid is rather distributed between several bases than combined exclusively with either."

I may allude, in passing, to a curious observation which has been made by Dr. Struve, the proprietor of an extensive establishment at Brighton, devoted to the manufacture of artificial or imitation mineral waters. He finds that in mixing the saline solutions with water, not merely the proportions of the ingredients, but also a certain order of mixing them, must be observed, otherwise the water will not have in all cases the same taste—a proof, if the observation be correct, that so trivial a circumstance as this may determine the nature of the decomposition.*

During the last year or two, an able English chemist, Dr. Gladstone, has occupied himself with this subject, availing himself, for the purpose, of the variations in the tint of coloured saline solutions when mixed with other salts, or diluted with water; and his results, though not absolutely conclusive, tend, I believe, to establish the truth of the opinion above advanced by Dr. Turner, that the acids and bases in a mixed solution are distributed in a more or less complex manner among each other, instead of being paired off two and two, under the operation of simple affinity.[†] Indeed, in the case I previously put, of three acids and three bases, it is quite possible that every one of the nine possible forms of combination may exist, in various proportions, at one and the same time in the same liquid. It is clear, therefore, that the ordinary mode of exhibiting the constitution of mineral waters, by arranging all the acids and bases as combined to such and such salts, is unscientific; it is conventionally adopted for the sake of distinctness, and because the public, for whose benefit these analyses are generally made, require something easily intelligible. The misfortune is, that as every one is left pretty much to follow his own method of grouping, different experimenters, who may have each made an equally perfect analysis of the same water, may exhibit their results in so very different a form, that no one would be able to divine, from mere inspection, that the water analysed had been even similar, still less identical in the several cases.

To chemists themselves the circumstance does not much signify, as they are able, by a few minutes' calculation, to re-arrange the constituents in any way most agreeable to their views; but the public are liable to be misled by it, and to imagine that all such cases of apparent discrepancy must arise from incorrectness or want of skill on the part of some or all the operators.

But the best way by far to avoid misconceptions of this kind, is to give, first of all, the positive results of the analysis, the actual quantities of each acid, base, or other constituent that have been obtained, and then, in a separate table, to arrange them according to such system as may be preferred. The figures in the first table can then be compared directly with those in another, which gives the analysis either of the same or of any other water. It is also to be regretted that no uniform standard of quantity of the water to which to refer the ingredients has been adopted. The standards used are not even of the same nature, some being of weight, some of measure. The former is the most scientific, and was used by Berzelius and many of the Continental chemists, the quantity of water assumed being usually either 10,000 or 1000 parts. In Germany

* See "Miller's Elements of Chemistry," 1856, part II. p. 1093.

† A summary of the latest experiments on this subject by Dr. Gladstone, and by Malaguti, will be found in the second volume of Dr. Graham's Chemistry; but by far the most complete and exhaustive view of the whole subject is given in the first volume of Gmelin's "Handbuch der Chemie," a translation of the latest edition of which is now under publication by the Cavendish Society.

the Prussian Civil Pound of 7680 grains, equal to 16½ oz. avoirdupois, is made use of. But a standard of measure is now most commonly used on the Continent; this is generally the litre of about 35 fluid-ounces. In England the variety is most perplexing; in the older analyses the wine pint is used, containing 16 fluid-ounces of 455·6 grain measures each; in the later analyses the imperial gallon of 70,000 grain measures is preferred, but sometimes the imperial pint of 20 fluid-ounces of 437·5 grain measures each, or 8750 grain measures in all, is used, and occasionally a bulk corresponding to 10,000 grain measures of water, or one-seventh of a gallon; the last will not, in the majority of cases, differ by more than a very few thousandths parts from 10,000 grains weight.

TECHNICAL CHEMISTRY.

On the Origin and Progress of the Phosphorus and Match Manufactures, by G. GORE.

(Continued from page 18.)

WHEN we consider that 1000 parts of urine contain scarcely one part of phosphorus, and of this probably only a portion was obtainable by the processes first in use, we shall not be surprised at the statement of Boyle that "the liquor yields but a small proportion of the desired quintessence," or at the price of 50s. an ounce charged by Hanckwitz for his product. Even an improved process, purchased and published by the French Government in 1737, yielded, under the direction of Hellot, Geoffroi, Dufay, and Duhamel only four ounces of phosphorus for every five hogsheads of the liquid.

After the death of Hanckwitz, in 1741, some experiments were made by Margraaf, Fourcroy, Vauquelin, and others; but no great improvement in the production of phosphorus appears to have been effected until 1769, when Gahn made the important discovery of phosphoric acid in bones. Margraaf had already demonstrated the individuality of this acid as early as the year 1740, and it only now remained to devise a process for extracting it. Scheele immediately did this, and various eminent chemists quickly succeeded in making various improvements in the method of working, and bequeathed unto us substantially the same process of manufacture as that now in operation.

The present sources of phosphorus are the bones of buffaloes and other animals, slaughtered in the great hunting-grounds of South America (the Pampas bordering the La Plata), where bones are used as fuel; exhausted "bone-black," or "animal charcoal" of sugar refineries; calcareous deposits of phosphate of lime, or "mineral guano" from the coast of Yucatan; and similar deposits from the Island of Sombremos; but the chief of these sources is the burnt bones from Monte Video, Rio Janeiro, Rio Grande, &c., and the animal charcoal of the sugar refineries. These various substances contain from 60 to 90 per cent. of their weight of phosphate of lime, or from 12 to 18 per cent. of phosphorus.

The phosphorus-yielding material, of whatever kind, having been suitably ground, a weighed quantity of the powder is placed in a large circular tub, lined with lead, with a mixture of oil of vitriol and water, and stirred by means of a revolving wooden stirrer, driven by a steam-engine, steam being admitted by a pipe into the mixture to facilitate the action of the sulphuric acid upon the powder.

The changes which bone-ash or other varieties of

phosphate of lime undergo in the above operation are these: the oil of vitriol or sulphuric acid gradually unites with the lime and forms sulphate of lime, and sets the phosphoric acid free; so that after the process there remains a semi-fluid mixture of a solid substance, sulphate of lime (gypsum or plaster of Paris), with a fluid body, phosphoric acid, separable by filtration.

The creamy mixture is now transferred, by means of ladles, to a filter or drainer, from which, with the aid of occasional stirring, the phosphoric acid filters into a vessel beneath. Water is added to the drained contents of the filter until the drainings cease to taste acid. The sulphate of lime or gypsum is then removed, in its damp state, to a furnace or other source of heat and dried, and constitutes a residuary product suitable for the manufacture of artificial manures.

The dilute filtered solution of phosphoric acid, containing some phosphate of lime and a small quantity of sulphate of lime dissolved in it, is transferred to leaden vessels and slowly evaporated over a gentle fire; the small quantity of gypsum then deposits itself upon the bottoms of these vessels and is removed by scraping. The liquid is deprived of as much more of its water as possible by further evaporation in similar vessels, and on cooling acquires the consistence of cocoa-nut butter.

The butter-like paste is then well mixed with a due proportion of powdered charcoal, and the mixture heated in furnaces of brick or iron until it is brought into as dry a powder as can be attained. The powder consists of charcoal, phosphoric acid (a compound of phosphorus and oxygen), a little phosphate of lime, and a little water, which is chemically combined with the phosphoric acid, and not capable of removal by the means yet applied.

We have already alluded to the intense heat employed by Boyle and Hanckwitz in their distillation of phosphorus: the same is also necessary in the present mode of manufacture. The vessels in which the phosphorus is separated consist of a number (about ten) of small retorts, of a convenient shape, carefully constructed of the most refractory fire-clay, narrowed at their mouths, and arranged nearly close together in a horizontal row in a furnace, somewhat similar to the retorts in a gas-works. They are placed in a nearly horizontal position, with their open ends slightly raised, and in a furnace so constructed as to subject them to nearly a white heat.

The black powder is introduced into the retorts when the latter are comparatively cool, and the retorts are about half filled with the mixture. Bent pipes, open at both ends, are inserted, air-tight by means of clay, into the mouths of the retorts, and their outer ends dip into warm water, in cast-iron basins, placed to receive the distilled phosphorus. I may now incidentally remark that all the manipulations with ordinary phosphorus in its simple and separated state are performed under the surface of water, otherwise it would quickly inflame and be reconverted into phosphoric acid.

The heat of the furnace is gradually raised, and in the course of some hours phosphorus begins to distil over, and accumulates in a melted state in the basins of water. The fire is still further raised, by gradual means, until a most intense heat is obtained; the phosphorus then distils rapidly. The heat, after being thus continued as long as any more phosphorus appears, is gradually decreased, and the basins containing the crude phosphorus are removed. The time occupied in the distillation is, in some cases, protracted from forty-eight to seventy-two hours.

In this operation the charcoal, at a high temperature, combines with the oxygen of the phosphoric acid, forming therewith carbonic oxide and carbonic acid gases, which escape through the nose-pipe, and the phosphorus thus set free is converted into vapour by the heat and distils over into the receiving basins. At the same time, the portion of water not extracted by the preceding process is also decomposed, and its hydrogen set free, combines with some of the phosphorus and forms phosphuretted hydrogen gas. The inflammable gases, carbonic oxide, and phosphuretted hydrogen, are conducted away from the phosphorus basins by means of a pipe and consumed.

When the distillation is at an end the furnace is cooled down and the residuary contents of the retorts extracted. The residue consists chiefly of charcoal (of which there is always an excess) and of undecomposed phosphate of lime, together with a few impurities, and is used in the composition of manures, the phosphorus in it being of too difficult or too unprofitable extraction. From the penetrating and destructive character of phosphorus, the retorts require frequent renewing, some manufacturers, when the best fire-clay is not employed, not using them for more than one operation.

The appearance of a phosphorus distillery containing between 200 and 300 retorts, which we have frequently visited when in full operation, and the furnaces at their maximum heat, is somewhat fearful:—The long, yellow flames of phosphuretted hydrogen and carbonic oxide shooting forth from the escape pipes; bits of burning phosphorus spitting forth in fiery balls from little crevices or leaks at the mouths of the retorts; the incessant bubbling of the vapour of phosphorus and escaping gases in the basins of hot water; the almost unbearable heat from the furnaces on each side, and from the red-hot flues under foot; the intolerable stench of phosphuretted hydrogen and burning phosphorus; together with the acid fumes, and filthy grim aspect of the place, combined to produce an impression on our senses which we cannot fail to remember.

The small cakes of crude phosphorus, each weighing several pounds, are collected from the iron receiving-basins when cold and melted together under water. The impurities which were carried over from the retorts into the basins by the current of gases and phosphorus vapour, now settle to the bottom of the fluid mass, and the supernatant phosphorus is drawn over into shallow copper pans, containing a small quantity of hot water to prevent contact of air, by means of leaden syphons previously filled with hot water, and allowed to solidify.

The large cakes or cheeses of phosphorus thus obtained still contain impurities, and are of a dirty red colour, chiefly arising from the mechanical admixture of a red variety of phosphorus in small particles. They are broken to pieces under cold water, and the fragments placed in hot water contained in a leaden vessel (heated by steam), together with a bleaching agent. The phosphorus is stirred with the heated mixture until it is bleached, or its brownish colour is removed, which generally occupies two or three hours.

The liquid phosphorus is again drawn by means of syphons into shallow copper pans, and allowed to solidify. It is then broken under water, and the pieces are placed in hot water in a double-sided (or steam-jacketed) vertical iron cylinder, lined with lead, with a perforated bottom covered with chamois leather and canvass, and while in the fluid state pressure is applied to the phosphorus, and it passes through the leather, &c., into a vessel of hot water beneath, leaving the residuary impurities, red

phosphorus, &c., upon the cloth in the form of a dirty reddish substance of an earthy appearance.

The bleached and purified phosphorus is now cast into wedge-shaped pieces, or it is moulded into cylindrical sticks, half an inch in diameter, and ten inches long, by the aid of glass tubes immersed into the phosphorus under water, or by means of an apparatus with tubes specially contrived for the purpose. On some occasions the phosphorus is very brittle and difficult to draw into sticks, but if it is in a satisfactorily pure state it is as ductile as lead or soft copper wire. The appearance of the purified phosphorus in the form of wedges is that of very transparent wax or glass of a slightly greenish-yellow colour, but when in the form of sticks it usually appears colourless. It is needful on all occasions to protect the purified substance from strong daylight, otherwise it soon becomes yellow and opaque. For conveyance it is always packed in water, generally in tin cans, the covers of which are soldered air-tight.

The phosphorus we have described is that of the ordinary kind, but there is another variety equally pure discovered in 1848 by Professor Schrötter, of Vienna, which is produced as follows:—The ordinary phosphorus in its purified state is placed under water in a cast-iron boiler over a furnace; then melted, cooled, and the water removed from its surface. The vessel is then immediately and securely closed, air-tight (except a small iron-tube for the escape of vapour), by a cast-iron cover. The lid has a vertical iron tube, closed at its lower end, fixed in it, which projects downwards into the phosphorus, and is open at its upper end for the reception of a thermometer. Heat is now gradually applied by means of the furnace until the phosphorus is at about 450° Fahr., and that temperature is maintained for a greater or less period of time, according to the amount of phosphorus operated upon, and the mass is then allowed to cool. A quantity of about 200 pounds is kept heated about three or four weeks. After this process the vessel is opened, and the phosphorus, which has now become a hard, red brick-like substance, is covered with water, and extracted by means of iron bars, &c. This process of conversion requires to be conducted with great circumspection, otherwise (from overheating of the phosphorus) fearful explosions may ensue; experience has, however, shown that they may be almost wholly avoided.

For commercial purposes the red or amorphous phosphorus, as it is termed, is required to be in a state of fine powder; the stony fragments are, therefore, broken into small pieces under water in a mortar, and ground under water between pieces of mill-stone in a vessel supplied with a small stream of water, which carries off the finer particles in its overflow stream into a large tank, where they gradually subside, or into a filter where they are collected. A process is then resorted to for the separation of any ordinary phosphorus which the powder may contain.

(To be continued.)

PHARMACY, TOXICOLOGY, &c.

On the Detection of Croton Oils in Mixtures,
by JOHN M. MAISCH.

IT may be sometimes of importance to prove in a fixed oil the presence of croton oil. Its peculiar effect upon the skin will show it whenever it occurs in a considerable proportion. There is, generally, little danger of mistaking for it other oils of similar properties; as, for instance, the sulphuretted oils of mustard, garlic, &c.

which manifest themselves by their odour. Fixed oils, however, might contain a sulphuretted oil, with its odour masked by some other perfume, and in so small a proportion as to produce only after several applications a slight inflammation of the skin; croton oil might be present under similar circumstances, and the question would then occur, How are we to prove the presence of croton oil? We can readily prove the absence of sulphur, but this would not prove whether or not croton oil was contained therein, unless we were by distillation to remove all volatile matter from this mixture. Small quantities cannot be well analysed in this way, as the inflammation produced might be too slight; besides, this method would not be one easily executed.

In searching for a convenient and ready mode for proving in oily mixtures the presence of croton oil, I availed myself of the results of Dr. Thomas Schlippe's researches on croton oil, (*Annalen d. Chem. und Pharm.* cv.) who, without being able to discover the cathartic principle, found the rubefacient ingredient, *crotonol*, to be a resinous principle, which, together with other resins and free acids, is removed from the oil, by agitation with an alcoholic solution of caustic soda, and then separated by neutralising the solution with hydrochloric acid. This mixture of various components of croton oil possesses the property of reddening the skin in a high degree.

I have followed strictly these directions, sometimes substituting for the soda, caustic potassa, and sulphuric for hydrochloric acid, with the same good results. Experimenting, first, with mixed oils, containing from $\frac{1}{8}$ to $\frac{1}{10}$ of croton oil, I afterwards operated with olive and almond oil, containing one drop to the ounce. The quantity of caustic potassa is regulated according to the amount of croton oil, or, if unknown, in accordance with the effect of the oil upon the skin. For oils insoluble in alcohol, I have used 85 per cent. alcohol, adding to it a sufficient amount of an alcoholic solution of caustic potassa, and agitating well; after separation had taken place, I removed the alcoholic liquid, and added to it an equal amount of water, and a sufficient quantity of sulphuric or muriatic acid. Soon an oily liquid rises to the surface, which, when applied upon the arm, produces in the course of three or four hours not only inflammation, but also the pustular eruption peculiar to the effects of croton oil. If the quantity was small, the acidulated liquid was shaken with strong ether, the ether evaporated, and the residue applied.

For castor oil, and in the presence of volatile oils, I have employed diluted alcohol, mixed with an alcoholic solution of potassa, and omitted the dilution of the decanted alcoholic liquid. The results were equally satisfactory, and in this manner I have detected croton oil, in the so-called castor-oil capsules.

It appears to me possible that croton oil may in this manner be detected in the stomach of animals poisoned by it; but not having the leisure for further experiments at present, I shall have to defer this subject until some other time.

According to Dr. Schlippe, croton oil contains about 4 per cent. of crotonol, and it is therefore necessary to operate very carefully, and without wasting anything. One accustomed to work with small quantities will not fail to detect it.

In conclusion, I will remark, that in pills and emulsions, croton oil is detected in precisely the same way; these preparations are first exhausted with ether, and the residue from the evaporation of the ether is employed.—*Amer. Journal of Pharmacy.*

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Weekly Evening Meeting, Friday, May 10, 1861.

The Duke of NORTHUMBERLAND, K.G. F.R.S., President,
in the Chair.

On the Relation of the Vegetable and Animal to the Inorganic Kingdom, by WILLIAM SOOVELL SAVORY, Esq., F.R.S.

AFTER some introductory remarks to show that plants and animals, when viewed in the relation in which they stand to inorganic substances, may fairly be regarded as together constituting one great kingdom of nature—the organized, the speaker proceeded to consider the relation of organized to inorganic bodies, in structure, in composition, and in function. He challenged the truth of the cell doctrine, and asserted that its leading propositions were not tenable. Not only are some of the simplest tissues of the most complex plants and animals formed without the direct agency of cells, but also that elaborate tissue, striated muscular fibre. He referred to the common *Amœba* or *Proteus*, as an example of a living form, simpler than an unicellular organism inasmuch as it exhibits no distinction of cell wall and cell contents; and to *Actinophrys*, as an illustration of a structure apparently cellular, produced by simple reticulation of a structureless amorphous substance. Vegetable cellular tissue has been generally supposed to be formed by the multiplication of distinct cells, but there is better evidence of its production by a similar process of reticulation of protoplasm. The simplest forms of life, and the simplest tissues of the highest, reveal no difference in structure,—no distinction of parts to the severest scrutiny, and cannot, therefore, as heterogeneous bodies, be distinguished from homogeneous inorganic matter.

Chemistry draws no line of demarcation between the organized and inorganic kingdoms. All questions of composition are of degree only, not of kind.

Life constitutes the grand distinction. The difference is infinitely greater between living and dead organic matter than between dead organic and inorganic substances. Without attempting to describe it, life may be distinguished by its effects. In life, when reduced to its simplest terms, and separated from all those elaborate details which invest it in the more complex forms, there exists a definite relation between destruction and renewal, a regulated adjustment between waste and repair whereby the condition is maintained, notwithstanding constant change.

Life is not a state of resistance. The proofs of this are clear and complete. Waste or destruction is a necessary, an inevitable condition of its manifestation. It is involved in every vital act. And the power of compensating for this waste or change, the repair or reproduction necessary to the continuance of life, involves that of assimilation,—the power of converting foreign matters into the structure of the organism: in other language, the power of appropriating food.

We cannot conceive life without including these two conditions—consumption and supply. Life is not a state of change only as opposed to stability; for this is simply a question of degree everywhere, and dependent on the conditions to which bodies are exposed. Neither dead organic nor inorganic bodies are immune from change. Nor is life peculiar as a process of repair only; for this may occur in inorganic bodies, as crystals, under favourable circumstances. But in life there is the constant and concurrent operation of these two processes, whereby it is distinguished from mere change on the one hand, and from repair on the other.

It does not appear that we can at present safely venture

further than this. If we attempt to define the vital process of nutrition, distinctions fail us.

The investigation of the phenomena of life has not been in any way assisted, our knowledge of the vital processes has not been in any measure advanced, by the assumption of what has been styled a "vital principle;"—an empirical term, which, like some others when employed in physiology, is, even at the best, equivalent to nothing more than the final letters of the alphabet in an algebraical formula: for it is, when used in its least objectionable sense, a mere expression of something unknown. But the assumption of such an agent or principle, however designated, annihilating or suspending the operation of forces acting elsewhere, has not proved altogether harmless in its influence upon the progress of knowledge. By referring all vital actions to this obscure agency, while nothing was thereby explained, inquiry was to a great extent, and for a long while, checked. Many dazzled by the idea that the nature of vital phenomena was exalted by thus associating them with some mysterious and peculiar principle apart from, and opposed to those agencies which act elsewhere, missed the grander conception, that even in the vital functions may be recognised the operation of forces, some of which, at least, are common to both kingdoms of nature; while, between these and others which appear to be peculiar to living tissues, it is probable that a relation may exist like that which prevails between the chemical and physical forces.

Again, it is needful to beware how we create artificial distinctions. Is there not much assumption involved in the confession that we are unable to construct the simplest form of living tissue? Men sometimes talk as if their powers were limited only by life. But can we construct a crystal any more than a nucleated cell? We may fulfil certain conditions, under which, as we have learned from experience, crystals are formed; but what is our share in the act itself? In like manner we may take a seed or an egg, and place them under circumstances in which they will develop. In either case we are acquainted with the necessary conditions, and we fulfil them. We can do no more.

The speaker concluded with some remarks on the fact that the tendency of advancing knowledge is to efface the lines of demarcation which have been hitherto drawn between the Natural Kingdoms.

Monday, January 7, 1861.

On the Importance of the Study of Chemistry,
by A. W. HOFMANN, LL.D., F.R.S.

(Concluded from page 11.)

I MIGHT go on for hours quoting illustration after illustration, but I must limit myself to pointing out a few of the advantages which the most important branch of human industry, *agriculture*, owes to our science. At an epoch when the resources of the agriculturist seemed almost exhausted, chemistry offered her hand, to lead him up a new ascent of improvements. An accurate study of the composition of plants, taught us the actual nature of their food,—that it was partly obtained from the atmosphere, and partly from the soil. It taught, likewise, that while the nutriment derived from the air (identical for all plants), is continually restored to it by the never-ceasing processes of respiration, combustion, and putrefaction; the mineral aliment (varying with each vegetable species), is drawn from a source which is liable to exhaustion. The knowledge of the importance, to the development of plants, of a due supply of their mineral constituents, implied the recognition of the necessity of faithfully restoring to the soil such inorganic matters as are removed from it in our crops. This principle sealed the pledge of alliance be-

tween agriculture and chemistry. To keep up the fertility of his fields, the cultivator of the soil had to make himself acquainted with its general composition, as well as with the nature both of the particular substances, which he is annually extracting from it, and of those with which he must supply the loss. For each of these purposes the aid of chemistry became indispensable to the farmer. Davy's excellent work on agricultural chemistry first called the attention of the more intelligent British farmers to the value of chemistry in the improvement of their art, but it is only within the last twenty years that the attention of agriculturists has been generally directed to the subject, more particularly by the works of Liebig and Boussingault. The nature of manures once clearly defined, almost every agricultural improvement at which practice had arrived by slow degrees, received a satisfactory explanation, whilst a variety of improved applications necessarily suggested themselves. The principles of fallowing and of the rotation of crops, and the theory of soil-burning, are no longer mysteries; the action of lime, of wood ashes, and of bones is now perfectly intelligible. In this country, too high a value cannot be set upon the discovery of new sources of material convertible by the farmer into human food. Chemistry has put us in possession of the excreted wealth, which centuries had accumulated in the islands of the Pacific; and if the means which it has suggested for preventing the enormous waste of valuable matter perpetually and irrevocably swept away by the Thames and others of our large rivers, have not as yet been perfectly successful, it has enabled us to substitute for natural manure, artificial products, for the components of which the refuse of every trade and manufacture is now carefully sifted. Perhaps there is no more striking illustration of the value of the aid which agriculture has derived from her new ally, than the success which of late has attended her search for mineral manures. This search, directed by the philosophical interpretation of a few isolated facts, has been rewarded by the discovery of considerable quantities of phosphate of lime in various parts of England; thus realising the prophetic anticipation of Liebig, that "in the remains of an extinct animal world, England is to find the means of increasing her wealth in agricultural produce, as she has already found the great support of her manufacturing industry in fossil fuel, the preserved matter of primeval forests, the remains of a vegetal world."

Nor is the increase of his vegetal produce the only object in the pursuit of which the farmer relies upon the counsels of the chemist; in the feeding and fattening of his animal stock, he stands in no less need of his instruction.

And here we may briefly allude to the benefits, which *physiology, pathology, and medicine* in general, have derived, and must still further derive, from the prosecution of chemical inquiry. The investigation of the food of plants was followed by a no less vigorous scrutiny of the food of animals. The materials consumed by animals were shown to fulfil two distinct purposes in their economy, enabling us at once to separate into two distinct classes the substances supplying,—each respectively,—the aliments of nutrition, and those of respiration. In vegetal fibrin and albumen, we became acquainted with a group of nitrogenous compounds, which we find again in the animal organism as the chief constituents of the blood. These materials, prepared by vegetal life, the herbivorous animal receives and assimilates into its blood, to supply the constituents of its different organs and structures.

Again, we have a series of substances, such as fat, sugar, gum, starch, &c., which, though not truly to be called nutriments, as having no part in the construction of the body, are no less essential to the maintenance of life. These substances serve the process of respiration; combining with the oxygen inspired by the animal, they continually compensate the loss of temperature, and thus become the source of animal heat. And here presents

itself one of the most interesting subjects for contemplation,—the animal organism in its relations to the surrounding atmosphere. The full appreciation of the effect of air and temperature on the animal system, was a most important step towards a true understanding of the conditions of health. A vast number of diseases originate in disturbances of the relation between the living system and these influences, the intimate knowledge of which affords to the physician the simplest, safest, and most efficient means of preserving health and of curing disease.

Valuable as have been the fruits of chemical inquiry, still more may be expected from the further prosecution of this study. The notion that the action of most of our medicines is chemical, is daily growing into a general conviction. We admit that with every change wrought by pharmaceutical agents in the state of our organism, there occurs a corresponding change in its composition, resulting from their reaction on one or more of its constituents. But of these transformations, which doubtless could be expressed in numbers as definitely as can our laboratory-processes, how few are we in a condition to explain; in how few instances has the physician even a vague conception of the mode in which any medicine performs its office! Nobody doubts the power, which the principles of the Cinchona bark, of the tea and coffee, exert upon the living body, but we are perfectly in the dark as to the way in which they act upon the animal economy. But if we meet with a series of similar substances in several animal fluids: e.g., *urea* and *creatin*, almost constantly present in urine; *glycogen* generally; and *cystine*, occasionally, excreted in the same liquid, and if we find that all these substances exhibit in their chemical relations a close analogy with *choline* and *lecithine*, we begin to feel a sort of anticipation of the manner in which these agents may act upon the system. Such examples illustrate at once the nature of the aid which the therapeutics may confidently expect from the progress of organic chemistry. Medicine some years ago found itself in a predicament very similar to that of agriculture at the same period; its resources appeared to be in a state of exhaustion, the rich capital of facts accumulated in the department of organic morphology by the industry of the anatomist, and by the acumen of the physiologist, could not yield its full fruits until an equivalent of knowledge had been drawn from the study of bio-chemical phenomena. This state of things, however, is rapidly changing; associated with chemistry, medicine no longer draws the veil of vitality over processes, the mystery of which may be unlocked by the key of analysis; it no longer shrinks from climbing, step by step, the ladder of recognition, because its upper extremity, disappearing among the clouds, seems to rise for ever beyond the grasp of inquiry. The special zeal with which the field of organic chemistry has been cultivated during the last thirty years, the simple and accurate methods which we now possess for determining the composition of organic products, the amount of analysis actually performed, and, more than all, the still untiring energy of the numerous labourers in the same field of investigation, hold out the promise that the connexion between medicine and chemistry, becoming daily more intimate, will be productive of benefits, the importance of which we can scarcely venture to estimate in the present state of our knowledge.

I have thus endeavoured to indicate some of the most remarkable features of the new field, into which the present generation has been conducted by natural sciences and especially of chemistry. I have tried to sketch the prospects, which a continuation of these labours promises to open before us. It remains to me now to consider the cultivation of chemical science under its other equally important aspect, as the unfailing source of the purest and highest intellectual enjoyment, and as a means of mental training, more effectual perhaps than any other discipline.

If poetic antiquity endowed with a new soul him who learnt to speak the language of another people, how shall we find a fit term to express the sharpening of our perception, the enlargement of our views, the opening of a perfectly new sphere of vision, accruing from the acquisition of a language which unfolds to us the comprehension of nature? Phenomena so common that we are accustomed to pass them by almost with indifference, how are they changed,—I might say ennobled,—by the light that science has shed over them! True it is that the guiding hand which, according to immutable laws, rules over the economy of nature may be recognised without the aid of science. It is visible to everyone who, with an open eye, looks into the world; but no one familiar with the mutual relations by which nature's phenomena are linked together, could deny that with each step forward in the field of research, the conviction becomes more deeply rooted, and that each new observation discloses a new source of the most elevated contemplations.

When glancing, in a former portion of this lecture, at the benefits arising to agriculture and medicine from the progress of chemistry, I have already hinted at the inquiries which have for their object the examination of the chemical conditions of vegetal and animal life, and at the light which they have thrown upon the true nature of respiration and nutrition. I am inclined to look again at these inquiries from a different point of view. They have taught us that animal respiration is a true process of combustion; in order to secure the necessary warmth, we have to burn at every moment a part of our body; this source of heat lasts so long as we supply to the seat of combustion continually renewed fuel; so long as the alternation of breathing maintains the supply of the necessary amount of oxygen, and accomplishes the removal of the products of combustion, i.e. of water and carbonic acid. With each respiration the animal robs the atmosphere of a certain quantity of oxygen, and introduces into it a proportionate bulk of carbonic acid. If we consider that the endless processes of combustion, carried out for domestic purposes and for the purposes of industry, produce the same effect; that, lastly, the transformations of organic matter, which we designate as putrefaction and decay, are, in many respects, nothing but processes of slow combustion: it is evident that the unlimited continuance of these conditions must gradually involve a change in the constitution of our atmosphere. Such a change has not yet been observed. It has been justly argued that the immense space of the atmosphere necessarily renders changes of this sort extremely slow, that our analytical methods are not sufficiently accurate, that our experiments do not extend over a sufficient length of time; nevertheless, who could fail to perceive that the compensation is furnished by the difference of conditions which govern the life of the plant in contradistinction to that of the animal? With its leaves, as with so many lungs, the plant withdraws the carbonic acid from the air. Under the influence of sunlight the carbonic acid splits into its constituents—the carbon is employed in building up the plant, whilst the oxygen is returned into the atmosphere. The plant is referred, for its support, to the compound which the animal ejects from its organism as no longer serviceable for the purposes of its life; but it requires only a part of this compound; the rest is set free, again to take part in the development of a new animal generation.

How simple and how wonderful are the means which Nature employs to fulfil her least, as well as her greatest designs!

A mine of interesting considerations is opened by the phenomena to which we have slightly adverted. The carbon of the plant is derived from the air, in which it exists in the form of carbonic acid. The carbonic acid is, as we have seen, partly furnished by the respiration of the animal; but in combustion as in decay a supply of

carbonic acid no less inexhaustible is secured to the atmosphere. But with how new a signification do these processes become endowed when we view them in relation to vegetal life! Combustion, which suggests to the ordinary observer the idea of destruction—decay, which we are in the habit of considering as the symbol of death, in the eye of the chemist are but changes of form bearing the germ of a new unfolding of life. Of all the changes which surround us in nature how different are the views we take, when once the study of chemical phenomena has convinced us of the indestructibility of matter, when once we have accustomed ourselves to consider, as fixed and unalterable, the sum of matter which, under the influence of the forces of nature in the processes of vegetal and animal life, is capable of assuming so endless a variety of form!

Contemplations of even a higher order have been attached to this recognition. No one is likely to deny the danger of attempting to refer the conditions of spiritual life to the laws of the material world, still, this speculation, which appears so consonant to ordinary conception, has been at all times indulged in. If in the gradual development of the cell, of the organ, of the animal,—each phase of which, although fulfilling a definite purpose of the present, nevertheless points to a future end as yet unfulfilled,—physiologists have seen but a special case of a much more general law, which governs likewise the unfolding and ultimate destiny of the human mind;—can we wonder that in the indestructibility of matter (the medium in which all these transformations are accomplished without a particle of it being lost),—chemical philosophers should with delight have imagined they had found a measure applicable to spiritual life, and that indestructibility of matter thus became to them a symbol of the immortality of the soul?

Thus we see emanating from the results of chemical inquiry a rich vein of considerations such as must be acceptable to every thinking mind; but these considerations are by no means limited to objects of general interest. No department of knowledge,—no branch of study,—can be imagined, but what might draw from the stores of chemical experience important solutions and significant suggestions. We find abundant proofs of this assertion in the chemico-agricultural, and chemico-physiological inquiries of Liebig, the general results of which are embodied in his admirable "*Familiar Letters on Chemistry*." The merchant, the political economist, the statesman, the ethnographer, the historian, each of them finds in this book numerous questions, in which he takes a lively interest, elucidated from the chemical point of view. Let us select a few examples from the superabundant material teeming on every page of Liebig's letters.

The ethnographer makes us intimately acquainted with the manners and customs of different nations, but how seldom does he go a step farther and attempt to explain such manners and customs (which are certainly not accidental) by referring them to the physical conditions of life of the respective nations, to the geographical situation or the climate of the countries which they inhabit! We obtain the most circumstantial accounts of the dietetics of different races, we learn with a sort of discomfort the small portions of, as we should think, unsubstantial nourishment which satisfy the inhabitant of a tropical country, while we lay aside with disgust the bill of fare of the Esquimaux, informing us of the quantity of blubber which constitutes the chief ingredient of his meal. How clearly has Liebig proved the natural necessity for this difference in the choice and quantity of food, by showing that it depends on the quantity of carbon, the combustion of which, under given circumstances, is required for the preservation of sufficient warmth! We have as little reason to admire the South for its moderation as to reproach the North for its extraordinary appetite. Every one who has lived some time in a tropical

climate recollects how his appetite diminished; whilst our Arctic travellers, as we see by their journals, become quickly reconciled to Polar diet. It is well known, moreover, that the beasts of prey of the Arctic regions considerably exceed in voracity the animals of the torrid zone.

If the historian inquires into the causes of the decline and gradual disappearance of the North American Indians, he is led to the perfectly correct conclusion, that a combination of circumstances must be involved in producing so striking a result. In any case he will learn with great interest the chemical conditions which are contributing to this catastrophe. Viewed in the light of chemico-physiological experience, the extinction of the red population must be ascribed to the animal food on which the Indian, as hunter, has especially to rely. The same experience has, in fact, taught us that a given surface of land, when serving the purposes of agriculture, is capable of supporting a number of persons from eighty to ninety times greater than when covered by forests inhabited by a nation of hunters. "Thus we see a scanty tribe of Indians dispersed over immense tracts of hunting ground, which must be considerably extended with the slightest increase of their number; and thus we understand the endless warfare which is decimating those red sons of the wilderness. It is no contest of principles, as with a civilized people, which, sparing the conquered, grants to him an honourable peace, but a mutual war of extermination—the desperate struggle for the morsel of bloody flesh which, like the beasts of his forests, the Huron tears with his teeth!" (Schödler.*)

It would be easy to multiply examples of the same kind, but I would rather allude, in conclusion, to the importance of the study of Chemistry, as a means of education apart from the advantages (accruing from the acquisition of such a vast variety of positive knowledge), which I have endeavoured to point out in the earlier parts of this lecture.

No one doubts the influence which mathematical pursuits have in developing the mental powers. No one can deny that the precision of thought, the correct inference from given premises, essential to progress in mathematics, gradually becomes a habit, which is soon transferred to intellectual labour of any other kind. The mathematician starts from certain fundamental truths, which, without external aid, he is capable of elaborating out of his own mind; and on this basis he piles up, step by step, the wonderful edifice of his science. It is this nature-like mode of construction, disdaining to raise another stone before the previous one is thoroughly secured, which constitutes the value of mathematics, as an element of mental training.

The pursuit of Chemical studies involves no less the development of the mental powers; it leads no less to precision of thought; it improves no less the habit of drawing correct conclusions, which, once acquired, is as easily transferred to other fields of mental labour. Chemistry, as a science, differs essentially from mathematics in this one respect,—that the truths which are its foundation cannot be drawn from the human mind itself. These truths are external to our mind, and can only be obtained by careful observation of the outer world; but, once our mental property, these experience-gathered truths afford a foundation equally adapted for the nature-like unfolding of a system of conclusions, which are not less logically linked together than the conclusions of the mathematician. The chemist has, however, this advantage over the latter:—whereas the mathematician has to find the guidance of his steps within himself, the chemist possesses in nature a mirror which, duly questioned, at every moment readily informs him whether he is still advancing in the right direction.

* Discourse on the Study of Chemistry as a means of Education.

NOTICES OF BOOKS.

Lights and Lighthouses: Report of the Commissioners appointed to inquire into the Condition and Management of Lights, Buoys, and Beacons.

THE blue book, detailing the evidence taken in the course of this comprehensive Parliamentary inquiry has recently been published in the forms of two massive volumes. These pages enter upon the discussion of several questions in physics, and include the relation of experimental results in many directions of scientific investigation, important in themselves and possessing great interest from the frequent recurrence of names of first-rate repute in science. Professors Faraday, Potter, Smyth, and Airy, Sir David Brewster, Sir John Herschel, Dr. Gladstone, Mr. Way, and Mr. Holmes have all been either directly called upon to assist in the inquiry, or their published investigations referred to for information. Foreign Governments and scientific authorities have also been consulted.

Her Majesty's Commission bears date December 8, 1858, and is addressed to Rear-Admiral William Alexander Baillie Hamilton, and Captain Alfred Phillips Ryder, of the Royal Navy; John Hall Gladstone, Esq.; Duncan Dunbar, Esq., Chairman of the London Local Marine Board; and Samuel Robert Graves, Esq., Chairman of the Liverpool Local Marine Board. The instructions conveyed to the Commissioners aforesaid charges them to inquire into the number, quality, and position of the lighthouses, floating lights, buoys and beacons on the coasts of the United Kingdom; to institute inquiries relative to the efficiency of the lights on our own coasts and those of our colonies, and the cost of constructing and maintaining these as compared with the expenditure for the like objects in foreign countries. Also to inquire whether the present system of management and control is well adapted for securing the most efficient lighting and buoying of the coasts of the United Kingdom and to suggest, if possible, any improvements calculated to ensure the more efficient conduct of that service.

The Report of the Commissioners is dated March 5, 1861. So great is the mass of evidence accumulated for the purposes of the inquiry that upwards of 900 closely-printed pages are taken up with the details of this laborious investigation. The great bulk of these particulars have no special interest for the readers of the CHEMICAL NEWS, but we purpose to devote a few pages in our Journal to the consideration of the scientific portion of the evidence, and to deduce therefrom the more important conclusions arrived at in the course of this inquiry.

With regard to the mode of taking evidence the Committee state at the outset that they have deviated from the system usually followed in similar cases by relying not only on oral evidence, but they have placed themselves in communication, through the medium of printed questions, with many individuals, both in this country and abroad, known to take interest in these subjects, and whose testimony would be regarded as worthy of confidence. On this point the Report sets forth that "*visd voce* examination is always best for extracting the truth from the unwilling, but written questions are best for obtaining deliberate opinions from men anxious to give them. A professional man could not be called before a Commission without offering to pay him not only for his expenses, but also for his loss of time. A number of answers to the same question admit of ready comparison, and that whenever a great number of skilled opinions are brought to bear on a single fact, if almost unanimous and from independent sources, greater reliance may be placed on the general conclusion than when a small number are consulted separately."

The Commissioners prepared accordingly a series of questions addressed particularly to men of science. These

were distributed among some fifty chemists, physicists, and mathematicians, and their replies were carefully collated and presented as an Appendix to the Report. Special investigations in several departments of experimental science have also been proposed by Dr. Gladstone. These refer to the production of light, its utilization; the space-penetrating power of differently coloured rays; direction and altitude of the light. In reference to fog signals, the study of the most favourable conditions for the transmission of sound. The relative durability of different building materials as applied to the construction of towers and beacons, constantly subject to the wearing action of the waves. Such, in a few words, is an outline of the questions considered in the Report before us. Many of the problems, as that of the economical production of the voltaic and magneto-electric lights, the later modifications of the lime-light have been the subjects of recent experiment, and are likely to meet with renewed discussion in the present day. On this account, therefore, we shall need no apology for introducing them in these columns to the notice of our readers.

In reference to "Circular No. IX." the general purport of the questions addressed to scientific men is as follows:—

I. The evidence of—

Optics.—(Production of Light.)

II. In lighthouses which are *easy of access*, do you think there is any method of producing light better than burning oil to the best advantage?

(Gas is used in some harbour lights. The magneto-electric light has been under trial at the South Foreland, and several other inventions have been proposed.)

III. Taking into consideration the difficulty of transport to lighthouses in remote positions, and the danger which results from an accidental extinction of such light, do you think that the method you have referred to could safely be substituted for oil in lighthouses so situated?

Utilisation of Light.

IV. Revolving Lights, &c.—What optical arrangement do you consider best for showing to an observer placed on the horizon, or at any point within it, for short periods, recurring at intervals, the greatest possible quantity of the light produced by the combustion of a given quantity of oil, or by any other given method?

(Metallic and other reflectors, polyzonal lenses, ground, and the same cast, totally reflecting prisms, and combinations of these, are used, or have been suggested.)

V. Fixed lights. What optical arrangement do you consider best for showing continuously and simultaneously to observers on the horizon, and at any points within it, the greatest possible quantity of the light produced by the method to which you have referred?

VI. Do you consider the methods which you have described applicable to floating lights, with or without modifications?

VII. Please to send any suggestions you may wish to offer relative to—

a. The manufacture of reflectors, including materials and shape.

b. The manufacture of glass.

c. The manufacture of lenses and prisms.

d. The placing of optical apparatus in lighthouses, so as to use the light produced to the best advantage, having due regard to the position and elevation of the light.

Colour.

VIII. Can you suggest any means other than the interposition of coloured glass for producing serviceable coloured lights?

IX. Have the goodness to send any suggestion you may wish to make relative to—

a. The manufacture of coloured glass.

b. The placing of coloured glass with reference to the light.

(Coloured chimnies, glass screens within the lens, the same outside, coloured panes in lanterns, and combinations of these plans, have been tried or proposed.)

X. *a.* What colours can, in your opinion, be seen at the greatest distance in all weathers, and at the same time can be most easily distinguished from each other, and from white light?

b. Is white light, or some coloured light, in your opinion, most serviceable in a fog? If the latter, what colour?

XI. Distance. Do you know any method by which the distance from a light may be determined?

a. When the height of the light above the water is known.

b. When the height is not known.

Mechanics.

XII. Can you suggest any improvements in

a. The construction of lighthouses in exposed or other situations?

b. The construction of beacons in similar positions?

XIII. Can you suggest any improvements in the construction of lamps, revolving apparatus, or other mechanical appliances now used in lighthouses, &c.?

Flotation.

XIV. to XVII. These questions relate to particulars of form, and to systems of mooring floating beacons.

Acoustics.

XVIII. What description or pitch of sound is most capable of penetrating a fog? What method do you consider best for producing such a sound?

XIX. What description of fog-signal would you recommend as the most serviceable?

(Gongs, automaton bells, and guns are used, as also reflectors and other contrivances for directing and condensing sound. Mechanical and steam whistles, &c., have been suggested.)

XX. What method do you think best for concentrating sound, or for throwing it in particular directions? Do you think that any method would enable mariners to distinguish with sufficient certainty the direction from which a sound proceeds?

XXI. At what altitude should fog-signals be placed, so as to be heard at the greatest possible distance?

Meteorology.

XXII. What is the elevation at which it would be desirable that light should generally be placed on the coasts of the United Kingdom, having regard to these facts, viz.: the higher the light the greater the distance to which the rays will reach before they are intercepted by the horizon? The lower the light the less likely it is to be obscured by clouds.

XXIII. Supposing the telegraph to be extended to certain lighthouses and light-vessels at salient points of the coast, what is the meteorological information which it would be most desirable to transmit to passing ships, and how and in what form could it be most readily received and communicated by light-keepers?

XXIV. Tide Signals.—What system would you recommend for general adoption in connection with lighthouses at the entrance of harbours, for indicating the state of the tide by day and by night, to persons in the offing?

(Various systems are now in use, including balls, flags, coloured lights, illuminated figures moved by the tide, &c., and others have been suggested.)

XXV. *a.* Are you aware of, or can you suggest any good system for identifying lighthouses and floating lights by day?

b. Can you suggest any improvement in the systems now used for identifying them by night?

In a future Number we shall proceed to a critical examination of the statements made in reply to the foregoing scientific questions.

Report on the Presence of Bisulphide of Carbon in Gas, addressed to Robert Jones, Esq., Engineer of the Commercial Gas Company. By FREDERICK VERSMANN, F.C.S. London: 1861.

[SECOND NOTICE.]

ALTHOUGH there can be no doubt that some sulphuretted hydrocarbons are generally present in coal-gas, it is quite certain that the principal sulphur-holding ingredient is the bisulphide of carbon. In whatever form, however, sulphur is present, the only practicable way of estimating the amount is by burning the gas in air, and so forming sulphurous acid, which is then converted into sulphuric and weighed as sulphate of baryta. The great difficulty hitherto has been to effect the condensation of the whole of the sulphurous acid. This would not, at first sight, appear to be a difficult matter; but experience has shown that it is not so easily accomplished.

The water produced in the combustion, when condensed, carries down with it a very small proportion of the acid. Some experiments made to ascertain how much would be secured in this way, gave an average of 24 grains of sulphate of baryta, equal to 3.28 grains of sulphur for the 100 cubic feet—a merely fractional part of the amount which we have shown was actually present in the gas. Even when the condenser is artificially cooled, the greater part of the sulphurous acid would appear to escape, and it is only by fixing it as sulphite of ammonia that it is possible to secure the whole. Several contrivances have been invented for effecting this, one of the most successful being that of Mr. Wright, who ensured the perfect combustion of the gas by burning it under a platinum rosette and then collected the products of combustion in a vessel containing ammonia. In this way over 40 grains of sulphur were found in 100 cubic feet of gas.

The plan which Mr. Versmann adopted is described as follows:—

"A small air and gas-burner was placed inside a very spacious glass-retort, open at the bottom, and afterwards closed by dilute ammonia, contained in a suitable glass-vessel. The retort was then connected with two Wolff's bottles, the first of which contained a solution of ammonia, and the second a solution of iodine in iodide of potassium; the gaseous products of combustion were forced through these liquids by means of a strong air-current, produced by a water aspirator, and thus absorbed.

"The solution of iodine was merely used in case some of the sulphurous acid escaping unabsorbed by the ammonia; but it was found in all these experiments that not a trace of it could be detected in the second bottle.

"The sulphurous acid combined with the ammonia to form sulphite of ammonia was then converted into sulphuric acid by a solution of iodine in iodide of potassium, precipitated by chloride of barium, and weighed as sulphate of barytes.

"This apparatus was connected with the neck of the retort; but a similar one was in communication with the body of the retort by means of a glass tube passing through the dilute ammonia into the body of the retort."

This description, it must be confessed, is not too intelligible; but we very well know, and shall presently illustrate, the difficulty of describing a system of apparatus without the aid of a drawing.

We have said before that we do not intend to question the perfect accuracy of Mr. Versmann's results; but we may just hint at the possibility that the rapid transit of a "strong" current of heated air through a bottle of ammonia would probably leave, in a short time, only a vessel of tepid water, whereby the advantage of the ammonia would be entirely lost; and further, that by passing quickly through the iodine solution, the sulphurous acid might perhaps escape oxidation and get away into the atmosphere undetected. This, however, is mere speculation, but the truth of it is rendered somewhat probable by

the fact that, in the experiments, which lasted a short time, Mr. Versmann obtained a much larger per-centage of sulphur than in those which lasted a longer time. For instance, the combustion of 118 feet gave only 2·96 of sulphur for 100 feet of gas, while the combustion of but 2 feet yielded at the rate of 6·7 in the 100 cubic feet.

The plan adopted in our own experiments is the contrivance of Dr. Letheby, and is at once the most simple and effectual means yet devised for estimating sulphur in gas. As no account of it has yet been published, we shall, with the Doctor's permission, describe the arrangement of the apparatus. This would be better understood with the help of a drawing, but for the present a verbal description must suffice. The objects are, to effect the combustion of the gas in a strongly ammoniacal atmosphere, by which means the sulphurous acid is fixed by the ammonia as soon as formed, and to condense the sulphite of ammonia. These objects are accomplished in the following way:—Two glass cylinders similar to those used for electrical machines are connected together by means of a wide glass tube fitted with bungs. To one of these cylinders is adapted the neck of a retort, which is curved downwards, and widened to admit for some distance the short chimney of a Leslie's burner, which is used to burn the gas. In the centre of the burner, and so as to come a little above the points of flame, a tube is fixed leading from a bottle of strong ammonia. From the end of the second cylinder a wide glass tube is carried a foot or two up into the air, to serve as a chimney and assist in creating a draught. With this apparatus it is only necessary to observe two precautions—to burn the gas very slowly,¹ and to keep up the supply of ammonia. The latter is of the utmost importance. It should be supplied so that the air escaping from the chimney connected with the second cylinder may always be alkaline. A large quantity of water condenses in both cylinders; but that one nearest the burner will be found to contain almost the whole of the sulphite of ammonia, some of which will be seen to have condensed in a solid form on the upper surface of the cylinder. After pouring out the solution, and rinsing out the cylinders and tubes, the sulphite is converted into sulphate of ammonia, and the sulphuric acid determined in the usual way.

Here we might leave this part of the subject, but we will just give the average results of three experiments in which the ammonia was imperfectly supplied, to show the great importance of a regular supply of this gas:—

	Cubic feet of gas burnt.	BaOSO ₃ per 100 cub. ft.	S. per 100 cub. ft.	Average S.
I.	17·6	222·6	30·53	27·9
II.	22	175·9	24·12	
III.	12·7	210·23	29·08	

With regard to the removal of bisulphide of carbon from gas, Mr. Versmann quotes with approval the opinion of Dr. Frankland published in the last edition of Ure's Dictionary, that there was little ground for hope that any practical means would be devised for its abstraction. He is a bold, if not a rash man, who, in these times, when the apparent impossibilities of one day are continually becoming the established results of the next, ventures to predict, or even to opine, the impossibility of accomplishing anything; and yet chemists are often indulging in vaticinations of the kind. Perhaps before Dr. Frankland had written the above opinion—certainly before Mr. Versmann had quoted it—the thing had been done, and by the use of the most simple means. On the 24th of May, 1860, Mr. J. E. Clift, from whose evidence we have before quoted, told the Committee of the House of Commons—and Mr. Versmann might have read it in the *Journal of Gas Lighting* for June 5—that Mr. Bowditch's process had been tried with success at Wakefield, and that he (Mr. Clift) was preparing to use it at Redditch.

¹ In all our experiments the gas was burnt at the rate of half a cubic foot an hour.

The London Companies, however, are strangely averse to improvements, when the use of them involves any payment to a patentee, and when it is found impossible to dispute a patent right (for which we are informed they have a common fund) they decline to use the process altogether. It remains, therefore, with the public to insist that the provisions of the Metropolis Gas Regulation Act are thoroughly carried out, and if the Companies do not choose to make use of the means for removing bisulphide of carbon, let them take care to prevent its formation.

We shall probably have something more to say on the same subject before long; but for the present we may conclude with the remark, that this Report is another illustration of the value of analytical certificates. In the gas which Mr. Versmann examined for the Commercial Company he found a maximum of 6·7 grains of sulphur in 100 cubic feet. In the gas which the Company supplied to their customers, after the publication of this Report, we found an average of 57·38 grains of sulphur in 100 cubic feet!

NOTICES OF PATENTS.

Sheet Iron. D. A. MORRIS.

THE intention of this patent is to produce on surfaces of sheet iron a hard, black, enamel-like coating, which is said to have great protective action against corrosion and the formation of rust, and also to give an improved appearance to the metal. The film of enamel is stated by the patentee to consist of proto-carbide of iron, and to be composed of one equivalent each of iron, oxygen, and carbon, or represented in chemical symbols, Fe O C.

The mode of proceeding contemplated in this invention would probably confer on the iron surface additional power of resistance against corrosive influences. But, inasmuch as the nomenclature adopted in the specification is a little ambiguous, we are unable to offer a more precise opinion upon the merits of the proto-carbide of iron containing oxygen as a protective against rust.

Colouring Matter. W. CLARK. (A Communication.)

IN order to obtain pure dye-extracts and brilliant lakes the inventor describes a new mode of treating madder and other tinctorial substances, whereby the more permanent colouring matters are purified from certain associated constituents, which interfere with the brilliancy of the dye. This end he proposes to accomplish by acting on the madder roots or powder with aqueous solution of sulphurous acid, to which a small proportion of sulphuric or other mineral acid has been added.

The principle of this process would appear to be susceptible of wide application, for among those colouring matters which are distinguished by their ephemeral character many are known to be bleached or entirely destroyed by sulphurous acid, while another more permanent class are able altogether to resist the action of this chemical agent.

Separating Copper from its Ores. P. SPENCE. (Not proceeded with.)

THE method of extracting copper described in the specification is applicable to all the sulphuretted ores of that metal, and to the poorer class of residual products obtained in the process of manufacturing sulphur and sulphuric acid from ordinary pyrites. The inventor, in dealing with any of these materials, grinds them to the state of fine powder, which is then subjected to a process

of roasting, at a moderate temperature, in a reverberatory or other suitable furnace. By this treatment the copper is mainly converted into sulphate, which may now be extracted by water, and in this manner separated from iron and the other ingredients of the ore.

The leading features of this invention are precisely identical with the process of treating copper ores patented many years since, and put into operation in this country by the Messrs. Bankart. It has long been remarked that a considerable loss of metal was experienced by the admission of rain to the heaps of roasted ore lying about the copper smelting works; and that iron tools left accidentally exposed to the drainage from these heaps invariably became coated with copper. This old observation appears to have suggested the several modifications of this general system of treatment, which have, from time to time, been proposed.

Obtaining Products from Coal, Gas-tar, Gas-pitch, Coal-tar, Asphalt, Resin, &c. E. PULS.

For the purpose of obtaining products from either of the materials above named, the inventor mixes them with a mineral acid, or with any oxidizing chemical agent, and then subjects the mixture to distillation in any convenient apparatus. Solid materials, such as coal, pitch, or asphalt, should first be broken into small pieces, or even reduced to coarse powder. On account of its low price, sulphuric acid is the oxidising agent generally preferred by the inventor; and in its use this acid requires to be intimately incorporated with the solid substance exposed to its action; but if a fluid, such as coal-tar, be the material employed, it is considered desirable to modify the action of the acid by previously mixing this latter with powdered charcoal, or with any other substance in a fine state of division which will not neutralise its effects.

It would be difficult to define exactly the nature of the chemical products obtained in these processes. Sulphurous acid would in all cases be liberated; but the nature of the fluid products of the distillation must vary not only with the different materials experimented upon, but will depend also on the proportion of acid or oxidising agent employed.

Manufacturing certain Gases applicable in generating Heat and Light, and in Bleaching. C. BINKS. (Not proceeded with.)

This invention has reference to the economical production of chlorine and oxygen gases, and is based upon the powers of affinity exerted at high temperatures between certain oxides and the elements of water and of hydrochloric acid. For the production of oxygen gas two methods are proposed. The first depends upon the decomposition of water, in the form of super-heated steam, by the combined agency of chlorine and of a substance capable of uniting with the hydrochloric acid produced. The second method consists in liberating oxygen from the brown or black peroxides of manganese by the action of chlorine assisted by a moderate heat. In regard to the production of chlorine the new process is based upon the decomposition of hydrochloric acid at a high temperature by the conjoint action of oxygen gas and of a material having an affinity for the elements of water.

In the foregoing specification the interesting alternations of chemical affinity appear to have been correctly defined, but in considering the expediency of the methods proposed for the economical production of oxygen and chlorine, we incline to the opinion that the recent suggestion of Deville relative to the preparation of oxygen, and the older methods of producing chlorine will maintain the advantage.

CORRESPONDENCE.

The Great Fire.—Storing Nitro.

To the Editor of the CHEMICAL NEWS.

SIR,—There are many facts well known, but the practical application of which to the ordinary affairs of life is but too often little heeded till some circumstance happen that fully impresses the necessity of making use of our knowledge. The recent great fire in Tooley Street, and the somewhat similar catastrophe which took place not long ago at Gateshead, will at once point to the fact that nitre must not be stored in the same warehouse with inflammable materials—as at Gateshead with sulphur, and in Tooley Street with oil, tallow, &c. Nitre, or saltpetre, is perfectly harmless by itself, and cannot be set on fire; but if sulphur, oil, tallow, or any other burning substances, be in contact with it, then a compound is produced having all the dangerous qualities of gunpowder, of which nitre is the active ingredient. Knowing these facts, it will be obvious that our warehousemen must in future store nitre in such warehouses as contain only incombustible materials. No amount of fire cement, iron doors, or brick walls, will save from destruction a warehouse on fire if it contain nitre and any other body that is inflammable, under ordinary circumstances. As I have before said, nitre is harmless enough by itself; and thus, by your kind aid, calling attention to this known fact, I leave the officers of the Insurance Companies to compel its being warehoused in separate and appropriate warehouses, away from anything that will burn.—I am, &c.

SEPTIMUS FISHER.

Chilswick.

Pure Sulphuric Acid.

To the Editor of the CHEMICAL NEWS.

SIR,—In reply to the inquiry of your correspondent "A Subscriber," in your Journal of the 29th ult., I shall be happy to supply him with pure sulphuric acid in any quantity and at any time if he will favour me with his address, as I am always making it, and have at this present time upwards of a ton weight in stock.

I am, &c.

PHILIP HARRIS.

Chemical Works, Bull Ring, Birmingham.

To the Editor of the CHEMICAL NEWS.

SIR,—In reply to the letter of "A Subscriber," in your Journal of the 29th of June last, I beg to inform him that I will supply any quantity of pure sulphuric acid, free from traces of any foreign matters that are injurious, at a very moderate cost. The cause of the inferiority of English acid of the present day is owing to the almost universal use of pyrites instead of the best Sicilian sulphur. The latter is only used at my Works.

I am, &c.

F. C. NORTON.

Oil of Vitriol Works, Bow Common, London, E.

The Sale of Poisons.

To the Editor of the CHEMICAL NEWS.

SIR,—The discussion which is taking place in your columns on the above subject cannot but be productive of good; it would be an injustice to the public if such an important matter were allowed to remain quiet. The Correspondents in recent numbers of your Journal very properly insist upon the importance of all persons who commence the business of chemist and druggist having a "Certificate of Competency." You refer (in a note appended to one of the communications) to the Pharmaceutical Society as an authorised body whose organization and

requirements are complete; but are you, or are many of your readers, aware, that a scheme is being discussed by the Council and Members of that Society for the introduction of members who have not passed any examination? the sole object of which departure from the original rules of the Society seems to be to increase their funds, which are found to be flagging.

Now, I submit that, should such an innovation take place, the Pharmaceutical Society will lose ground considerably in public estimation. The desire on the part of the Pharmacutists to raise the educational *status* of chemists was very praiseworthy, and they might eventually, by increasing the numbers of their members, and securing public favour to themselves, have occupied the entire ground now so unequally shared—i.e., in excess—by unqualified pretenders to the trade.

As the case is, however, with regard to that part of the dealings of chemists, which relates to the sale of poisons—it seems high time that the Legislature should enact some restrictive measures as to the kind of persons who may or may not embark in that deadly trade. As well as some compulsory clauses respecting the use of such methods in the dispensing and sale of poisons by authorized chemists that shall seem best calculated to protect the public from that class of accident, which has become but too common of late.

The most effectual plan that has been devised, is the use of the "safety or drop bottles," a description of which appeared in your columns some months ago. I would strongly urge upon the public the necessity of taking this matter into their own hands, and in default of compulsory legislation to that effect, they should, when ordering liquid poison of any description, require it to be sent out in the "narrow-necked bottle;" such a demand would be irresistible, and the object in view would be accomplished.

I ought to apologise for the free manner in which I have expressed my views, with the expectation of a place in your columns; knowing that you do not favour legislation on the subject, but that you advocate "free trade" in drugs; however, you must remember that "free trade" in poisons means free trade in death, for not only does it not afford any protection against accident, but it offers great facilities to the intentional poisoner, and gives a great increase to crime.—I am, &c.

PRO BONO PUBLICO.

Chemical Notices from Foreign Sources.

II. ORGANIC CHEMISTRY.

Oxyacanthine.—Karl Wacker gives (*Wittstein's Viertel-Jahresschrift*, Bd. x. s. 177) a full account of oxyacanthine. This body was discovered by Polex in the bark of the root of the common berberry. The author prepared it from the precipitate produced by carbonate of soda in the mother liquor from which berberine had separated. The precipitate forms a catechu-like mass. This is treated with water, acidulated by hydrochloric acid, the solution is filtered from the resinous matter separated, and then precipitated by ammonia. This precipitate is washed, dried, and then extracted with ether. The ethereal solution is allowed to evaporate to the consistence of an extract, which is dissolved in distilled water, with the addition of hydrochloric acid. This solution is largely diluted, and then saturated with ammonia, whereby a tolerably white precipitate of oxyacanthine is produced. By repeated solutions and precipitations it is obtained quite pure and snow-white.

Pure oxyacanthine, $C_{32}H_{23}NO_{11} + HO$, is a dazzling white powder, which, when kept in a shady place, undergoes no change; but when exposed to direct sunlight becomes of a yellow colour. This, however, as in the case of santonine, appears to be only a molecular change, for the solution of yellow oxyacanthine in an acid is again

precipitated white by an alkali. It can be obtained in the crystalline state by allowing a strong ethereal or alcoholic solution to evaporate spontaneously. The taste is a pure bitter, which does not long remain. It melts to a yellow liquid at $139^{\circ}C$, and at a greater heat gives off empyreumatic vapours, leaving a residue of shining carbon. Chloroform dissolves it easily under all circumstances. Strong hydrochloric acid dissolves it quickly, without occasioning any change of colour. Strong sulphuric acid forms a clear solution, which has a shade of yellow. Concentrated nitric acid gives a brownish-yellow fluid, from which warty crystals soon separate. Chromic acid is reduced to chrome oxide. Chlorine water gives a yellow solution to which ammonia communicates a darker shade, but causes no precipitate. The behaviour of iodic acid is worthy of notice; if a small crystal be placed in contact with either pure oxyacanthine or a salt, and then a few drops of water be added, a smell of iodine is immediately evolved, and starch-paper, touched with the mixture, is coloured blue.

A solution of a neutral salt of oxyacanthine shows the following reactions. Ammonia gives a white precipitation which dissolves in a large excess of the precipitant. The other alkalis and their carbonates give a white precipitate; so does lime-water. Nitro-picric acid gives a lemon yellow precipitate; tannic acid a yellowish cloudiness; iodide of potassium a white, and an ioduretted solution of iodide of potassium a brownish-yellow precipitate. Sulphocyanide of potassium, and bichloride of mercury, give a white, chloride of gold a yellow, chloride of platinum a pale, greyish-yellow, and nitrate of palladium an orange-coloured precipitate. Ferrocyanide of potassium produces a white, the ferricyanide a sulphur yellow. Phosphomolybdic acid gives a yellowish white.

The salts formed by oxyacanthine are all white, and are obtained in warty or acicular crystals, with the exception of the acetate, which will not crystallise.

In conclusion, the author proposes the name of *Vinetin*, from *vinetier*, the French name for the berberry, because the word oxyacanthine calls to mind the *Crataegus oxyacantha* rather than the *Berberis vulgaris*.

Saligenine.—This body, say Beilstein and Seelheim (*Annalen der Chem. und Pharm.*, Bd. cxvii. s. 83), is best obtained pure by crystallization from pure benzole. From a hot solution it separates perfectly on cooling, for one part of saligenine requires 52 parts of benzole at $18^{\circ}C$. to keep it in solution. The sp. gr. of pure saligenine estimated in a cold saturated solution in benzole at $25^{\circ} = 1.1613$. Perchloride of phosphorus acts violently on dry saligenine. By the reaction of two molecules of the former on one of saligenine there are formed saliretine, oxychloride of phosphorus, and hydrochloric acid:—

Saligenine. $C_{14}H_8O_4 + PCl_5 = PO_2Cl_3 + 2HCl + C_{14}H_8O_2$ Saliretine.
Saliretine was attacked with difficulty by perchloride of phosphorus, and a chlorinated body was produced which contained no oxygen, but gave more chlorine than answered to the formula $C_{14}H_8Cl_2$. The analysis of this body gave C 33.12, H 1.11, and Cl 65.81 per cent. Dried at $150^{\circ}C$. Saliretine has at $25^{\circ}C$. the sp. gr. 1.1161.

By the treatment of saligenine with acetic acid anhydride, and some ether, in a sealed tube, saliretine is formed, which in this way is obtained pure with tolerable ease. The following decomposition-formula explains the reaction:—

Saligenine appears to form definite compounds with baryta and lime. It easily dissolves in baryta water, and from the solution evaporated in vacuo crystals resembling wavellite separate, which, dried at 100° , have the composition $C_{14}H_8BaO_6$.

III. TECHNICAL CHEMISTRY.

Preparation of Gun Cotton.—A chemist, who

does not give his name, has published (*Archiv. der Chem.*, Bd. oliv. s. 270) an account of a series of experiments which he has made on the preparation of gun cotton. The results he has arrived at may be summed up as follows:—The smaller the quantity of cotton wool operated upon the more easy it is to prepare a good gun cotton. An ounce of cotton wool he found was as much as could be manipulated with safety. The proportions found to give the best results were one ounce of cotton wool, 16 ounces of nitrate of potash, 12 ounces of English sulphuric acid (sp. gr. 1.84), and 12 ounces Nordhausen acid. Five minutes in this mixture was found to effect the change in the cotton perfectly. A longer exposure was not only useless, but mischievous. The temperature at which the action of the mixture goes on best is from 154° to 160° F.

MISCELLANEOUS.

The Cork Trade of Bordeaux.—There are at present in Bordeaux twenty-five cork factories, employing seventy-five workmen, using annually 3,396,846 lbs. of cork bark, and producing about 10,000,000 corks. 90,000,000 ready-made corks are obtained from the neighbouring places, Nèzac, Bayonne, and Provence. The cork trade of Bordeaux, therefore may be estimated at 100,000,000 corks annually, worth about 156,333*l*. Two-fifths of this quantity are exported to the French colonies, the United States, Chili, India, &c.; three-fifths are used in Bordeaux, at the average price of 1*l*. 4*s*. per thousand. These corks are divided into four classes—namely, the extra fine, used for champagne bottles, and sold for from 2*l*. to 4*l*. 16*s*. the thousand; the very fine used for bottles of wine of the first quality, and sold for from 1*l*. 4*s*. to 2*l*. the thousand; the fine, used for bottles of wine of the second quality, and sold for from 16*s*. to 1*l*. 4*s*. the thousand; and the common corks, used for bottles of common wine, and sold for from 2*s*. 4*d*. to 16*s*. the thousand. Nearly all of them are made by hand. There are so many difficulties and disadvantages connected with their manufacture by machinery that the use of machines is unprofitable. One class of workmen cut them into lengths, another turns them, and women are employed to separate them into the different classes named above. One cutter can prepare work for five turners, and one turner can make on an average 1200 a-day. The cutters are paid from 3*d*. to 4*d*. per thousand, and the turners from 1*s*. 2*d*. to 1*s*. 6*d*. per thousand; that is about 1*s*. 6*d*. a-day.—*Mechanics' Magazine*.

Glass.—Glass has become with us an article so singularly cheap and common, that we are apt to lose sight of its immensely diversified qualities; but if only considered from a philosophical point of view, we shall find that few of the substances which we have in daily use, either in a simple or compound state, can be compared to glass in point of importance and usefulness. Firstly, unlike any mineral, it is inodorous and clean to the fingers, and does not lose any of its weight by usage or wear; it is always transparent, whether in a cold or a red-hot state; it can take any shape whatever while in a state of fusion, and it retains it absolutely after it has cooled. It is capable of receiving the highest polish, and of taking any coloured tint, either on its surface or in its body; and it also has this peculiar and invaluable advantage, that it does not retain any taste of any liquid or acid it may have contained; it is the most flexible of substances while in fusion, and becomes harder than any pure metal when once it has become cold; lastly it is not liable to rust or to be consumed by fire. The innumerable applications of glass are such now, that it is difficult to imagine any one branch of industry or of manufacture which could be carried on a single day without the use of glass in one shape or another. To some of the

most important amongst the sciences, such as chemistry, physics, astronomy, the use of glass is a matter of absolute necessity; and in proportion to the gradual and increasing requirement of those last-named sciences, especially astronomy, it will be found that the glass manufacturer has been obliged to perfect his mode of manipulation, and, by the aid of chemistry, has of late years obtained such magnificent results that the field for astronomical observations has thereby been considerably enlarged.—*F. Joubert*.

Substitute for Silver.—Messrs. De Ruolz and De Fontenay have lately obtained, after several years' experiments, a new alloy, which may be very useful for small coin and for many industrial uses. It is composed of one-third silver, 25 to 30 per cent. of nickel, and from 37 to 52 per cent. of copper. Its inventors propose to call it *tiers-argent*, or tri-silver. Its preparation is said to be a triumph of metallurgical science. The three metals, when simply melted together, form a compound which is not homogeneous; and to make the compound perfect, its inventors have been compelled to use phosphorus and certain solvents which they have not yet specified. The alloy thus obtained is at first very brittle; it cannot be hammered or drawn, and lacks those properties which are essential in malleable metals. But after the phosphorus is eliminated, the alloy perfectly resembles a simple metal, and possesses in a very high degree the qualities to which the precious metals own their superiority. In colour it resembles platinum, and is susceptible of a very high polish. It possesses extreme hardness and tenacity. It is ductile, malleable, very easily fused, emits when struck a beautiful sound, is not affected by exposure to the atmosphere, or to any but the most powerful reagents. It is without odour. Its specific gravity is a little less than that of silver. An alloy possessing these properties must be very useful to gold and silversmiths. It can be supplied at a price 40 per cent. less than silver, and its greater hardness will give it a marked superiority. It may also serve as a substitute for gold-plated or silver-plated articles, which are now so common on account of their cheapness, but which will not bear re-plating more than a few times, and which are, in the long run sometimes more expensive than the pure metal. The new alloy, however, will be most useful for small coin. Its preparation and coining are so difficult that the coin made of it cannot easily be counterfeited. Its hardness would render it more durable than silver; and thus the expense of re-coining, and the heavy loss arising from the wearing of our silver coinage, would be greatly diminished.

ANSWERS TO CORRESPONDENTS.

C. Bades.—The tube in which the platinum wires are sealed, should have the air exhausted from it. The points are too close together, they should be eight or ten inches apart at least, and must be connected with the poles of a powerful induction apparatus. The price of a good apparatus of this sort (called a Ruhmkorff's coil) is very high. Probably, with the necessary batteries, one to answer your purpose would not cost less than 20*l*. You will obtain a better light by using charcoal points. The induced current does not give so strong a light. You can get American books of Samson Low, Ludgate Hill.

A Lady.—The subject of the crystallization of quartz is one of great interest to the chemist. We shall be glad to hear further particulars.

Dyeing Mixed Fabrics.—A correspondent is anxious to know how to dye a mixture of silk, or wool and cotton, with Magenta.

Solid Chloride of Manganese.—A correspondent writes:—"Can any of your readers inform me where to obtain a quantity of solid chloride of manganese? I am aware it is made in large quantity as a waste product, but cannot ascertain where, or at what cost it may be procured."

A Subscriber.—The *Journal of the Royal Institution* is not now in existence. The *Journal of the Chemical Society* appears every quarter, and the *Philosophical Transactions* once or twice a year, according to their bulk. The index to our first Volume is now out of print, and cannot be obtained except by purchasing a bound volume, of which only a few copies remain.

Books Received.—"A Guide to Croft Spa." By Miss D. Wilkinson. Dartington: 1861. "A Manual of Qualitative Analysis." By R. Galloway. Third Edition. London: Churchill. "Proceedings of the American Pharmaceutical Association for 1859." Boston.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Normal Variability of the Properties of Atmospheric Air,
by M. HOUZEAU.

THE ravages of certain epidemics, and the diseases which seem to be confined to certain localities have long caused it to be supposed that the air may contain injurious principles, and thus temporarily and at intervals acquire unhealthy properties which it does not possess in its ordinary state. The facts I am now about to communicate to the Academy show that this variability in the properties of the air breathed by human beings is much more frequent than is usually supposed, and that, instead of being exceptional, it may be said to represent the normal condition of the atmosphere.

If two blue litmus test-papers, of the same size, sheltered from rain and sun, are exposed to the air at the same day and hour, it will be observed that in country air they become completely decolorized in three or four days, while the paper retains almost all its colour if exposed, under the same circumstances, to the air of a town. (Comparative observations made at Paris and Montmorency, August 8, 1856, and at Paris and Nanteau, near Nemours, September 3, 1857.) Similar effects are produced if the operation is performed in two places on the same horizontal line, and distant from each other one or two kilometres only.

This curious chemical reaction is, so to speak, constant both in summer and winter, but its intensity is augmented when the atmosphere is violently agitated, as during tempests and hailstorms, and at the approach of a storm. I think that the attention of agriculturists and physiologists should be directed to this fact, as it shows that plants and animals are differently impressed by the air according to their situation.

The variability of the chemical properties of the air is singularly confirmed by other characters. If the decolorising action of the air is generally less intense in towns than in the open country, its property of permanently reddening blue litmus seems to follow an inverse order. Blue papers, exposed to the air, but sheltered from rain and sun, receive a fast red tint sooner in a town than in the country. In Paris, in 1856, as d'Arcet had remarked in London long ago, this phenomenon was normal in certain streets abutting on the Conservatoire des Arts et Metiers, and it was observed at Rouen in quarters furthest removed from manufactories,—in those parts nearest the hills covered with verdure in summer. It is true that the prevailing winds blow in that direction, and may thus bring with them the smoke of the town. The papers thus reddened preserve their tints when submitted to the action of an air-pump, or when heated in a tube to 100°. The action of the atmospheric acid on the coloured re-agent usually manifests itself forty-eight hours after exposure to the open air. The edges

of the paper first become red, and at the end of the third, fourth, or fifth day, the change from blue to red is complete. Generally, when the decolorising phenomenon above mentioned takes place in a town, it is preceded by the reddening of the re-agent; this seems to me very rare in experiments made in the country.

These differences in the properties of atmospheric air, examined at the same moment, and in a somewhat restricted radius, are confirmed, and, at the same time, made more obvious, by another re-agent, litmus paper of a wine-red colour, half of it being iodised. A paper of this kind will often turn very blue in twelve or twenty-four hours, and sometimes even in six in the portion impregnated with neutral iodide of potassium, and exposed in the country, and yet will undergo no alteration, even in a much longer time, if exposed to such air as circulates freely in a town about one kilometre from the country station. (Rouen and its environs, July 11, 1858; June 6, 1860.) For many reasons, the phenomenon is less surprising when it occurs in localities further apart and situated at different heights, as Paris and the villages of Laqueus, in Brie, and Nanteau, near Nemours (September 3, 1857), and as Rouen and Florence, in Italy, according to the observations which MM. Carina and Silvestri have been kind enough to make with my papers (December 20, 21, and 29, 1860). Furthermore, it has frequently been proved that this difference in the action of the air on the same re-agents is perceptible, even when the papers are only six metres apart on the same horizontal line, but separated by a house built in a treeless field. Thus, it sometimes happens that demi-iodised litmus placed to the north of a building the blue colour is far more intense than that placed to the south of the same building and at the same height. An exceptional case is very rare, at all events, within my field of observation. A similar result is obtained if the experiment is made at the two extremities of a vertical line. At Rouen, blue litmus became more thoroughly decolorised, and demi-iodised litmus became bluer at the summit of the cathedral than at six inches from its base, &c.—*Comptes-Rendus*.

On White Lead, by A. ADRIANI, M.D., Ph.D., F.R.N.I.F., &c., &c., Analytical Chemist and Lecturer at Edinburgh.

SOME time back I had occasion to analyse a sample of white-lead paint supplied by a most respectable firm, which sample I found to contain 21.9 per cent. of sulphate of baryta. Doubting whether the sample given me was really made by the firm it was said to have been supplied from, I obtained a small keg filled with the paint, and marked by the firm as being white-lead paint of first quality, which paint I found on examination to be identical in composition with the previous sample, containing fully 22 per cent. of sulphate of baryta. It therefore appears, that with the practice of mixing the

white lead with linseed oil, that of adulteration is keeping pace, it being a well-known fact, that the detection is rendered somewhat more difficult when, instead of being sold as a white dry powder, white lead is sold in the shape of a thick paste.

I take leave to quote here the composition of twenty-seven samples of white lead, as made in different manufactories of the kingdom of the Netherlands, and analysed within the last six years by Dr. Vlaanderen,¹ assistant to Professor Mulder at Utrecht. The hygroscopic water was not separately estimated.

	I.	II.		Calculated.	Equivalent.

	XVIII.	XIX.
CO ₂	12'9	12'9
HO	2'2	2'1
PbO	85'3	85'4

Calculated. Equivalent.

CO ₂	12'7	=	3
HO	1'7	=	1
PbO	85'6	=	4

or PbO, HO + 3 CO₂, PbO.

	XX.	XXI.	XXII.	XXIII.	XXIV.
CO ₂	13'1	13'5	13'5	13'2	13'0
HO	2'0	1'5	1'6	1'7	1'8
PbO	85'4	84'7	84'9	85'2	85'2

	XXV.	XXVI.	XXVII.
CO ₂	13'3	13'2	13'1
HO	1'8	1'9	2'0
PbO	85'1	85'0	85'1

Calculated. Equivalent.

CO ₂	13'4	=	4
HO	1'4	=	1
PbO	85'2	=	5

The larger quantity of water is no doubt due to hygroscopic water. Two only of the samples of white lead examined have the following composition:—

PbO, HO + 2 CO₂, PbO.

Ten gave this:—2 PbO, HO + 5 CO₂, PbO.

Seven gave this:—PbO, HO + 3 CO₂, PbO.

Eight gave this:—PbO, HO + 4 CO₂, PbO.

Dutch white lead, therefore, consists of 1 equivalent of hydrated oxide of lead, with 2, 2½, 3, and 4 equivalents of neutral carbonate of oxide of lead; 2 and 3 occur more rarely, but 2½ and 4 are usual.

The results here quoted are published by Professor Mulder in a Dutch work, containing the results of

¹ Now, and for some time since, in the island of Java, as Chemist to the Colonial Government.

researches made in his laboratory. In order that it should not be supposed that the samples analysed were select samples, Professor Mulder distinctly states, that he was sorry he could not find from what manufactories the samples had been obtained, so that he could not make sure of another interesting point, viz., whether in the same manufactory the white lead was always obtained of the same composition. The quantity of hydrated oxide of lead which occurs along with the carbonate of lead is by no means unimportant. At the desire of the party for whom I made the analysis above referred to, I do not publish the name of the firm who supplied the white lead directly. I made three analyses of the sample, and found that the carbonate of oxide of lead and the hydrate of the oxide of lead only amounted to about 60·5 per cent., the remainder being the sulphate of baryta and the oil. Neither chalk, nor sulphates of lime or baryta are found in the Netherlands, unless it be in small quantity in the soils: these articles, as far as wanted, are imported from abroad.

Rubidium and Cæsium.

ACCORDING to a communication made by MM. Bunsen and Kirchhoff to Professor Redtenbacher, both rubidium and cæsium, the two alkali metals recently discovered by means of spectrum analysis, have a great chemical similarity to potassium, differing from this metal and from each other in the degree of solubility of their double chlorides of platinum and potassium. At the boiling point, 1000 parts of water dissolve 49 parts of chloride of platinum and potassium, 6 parts of that of rubidium, and 3½ parts of that of cæsium. Rubidium is found in largest quantities in the lepidolite from Rosna (in Moravia), and with traces of cæsium in certain saline mother-liquors. Cæsium seems essentially confined to mineral waters, 39,600 litres of that of Dürkheim yielding 6 grammes of chloride of cæsium.

TECHNICAL CHEMISTRY.

Destructive Action of Minium on the Hulls of Iron Ships. Letter from M. JOUVIN to M. DUMAS.

THE observations I made last March on the iron hull of the imperial packet *Guienne*, are confirmed in every point by those furnished by the hull of the packet *Le Bearn*. At first sight there was such strong resemblance between the state of the two hulls, that they seemed identical; but by going into details the following differences were observed:—

The whole of the hull of *Le Bearn*, which has received a coating of minium, has become dull red; the vivid tint of oxide of lead is extinguished in a vague colour as if washed out; or as if the painting had been covered with a sort of grey glazing. On this ground scales of hydrated oxide of iron stand out in relief, and are just as numerous and large as in the case of the other vessel. On this occasion I found that the layer of oxide of iron was much thicker at the corners and edges of the sheet iron plates than elsewhere, although the friction must be greater on these prominent parts. This fact escaped my notice with the hull of the *Guienne*.

I think the bubbles are as numerous on the rest of the coat, if not so large as on the *Guienne*. These bubbles may be always divided into two kinds:—

1. Bubbles containing some drops of liquid.

2. Bubbles without liquid, and containing merely air or a gas.

The latter are remarkable for being covered at their base with minute crystals of lead, overlaid with a thin coating of hydrated oxide of iron or yellow ochre. The internal surface of the pellicle of which they are composed, examined with a lens, shows needles of chloride of lead in the midst of slight concretions, which have the appearance of "horn lead" of mineralogists. (*Kérassine*.)

The concretions of chloride of lead, which I found afterwards at the base of both kinds of bubbles, on the iron hull, imbedded in magnetic oxide of iron, the dark colour of which they relieve by their slightly amber tint.

The liquid contained in the other bubbles I have subjected to a more careful examination. Tested *in situ* it slightly reddens litmus paper. To the taste at first it is freely styptic and rough, a taste due to the ferrous chloride, as I said in my first paper; to this soon succeeds a sweetish taste, resembling a weak solution of acetate of lead. In my observations on the *Guienne* I recognised, by this taste, the presence of a dissolved salt of lead in the liquid contained in the bubbles. I did not mention it at the time, because I had not determined its nature.

In order to find out, I collected a certain quantity of the liquid by absorbing it with a piece of blotting-paper, when it became easy, by means of distilled water and re-agents, to determine that the liquid consisted of a solution of ferrous and plumbic chlorides. Do not these two chlorides form a true soluble saline combination? I am strongly inclined to this opinion. When occasion serves, I propose to revert hereafter to this study. One fact which my experience has taught me is, that solutions of ferrous chloride become, by contact with minium, charged with chloride of lead, as may have been easily foreseen.

The liquid of the bubbles, when exposed to air, quickly becomes covered with a thin pellicle of sesquioxide of iron, without precipitating the slightest trace of chloride of lead. This salt does not appear until only a trace of liquid remains at the bottom of the capsule. By means of the microscope, and even with a lens, it is easy to detect in the midst of the sesquioxide of iron the play of colours of the micaceous spangles of this salt, the deposit of which in the capsule seems to me to be effected in the same manner as if the bubbles were dried.

There was a degree of regularity in the disposition of the concretions on the hull of the *Guienne* which was not to be found on that of *La Bearn*. In other respects it presents exactly the same foliated structure; it has always externally and at the moment of immersion the same gray colour of the iron; then, under this thin envelope, yellow ochre; and at the base the dark green of hydrated ferrous oxide and ferroso-ferric oxides. In all these points the concretions on the two vessels were almost identical. We shall likewise soon establish their chemical identity.

To conclude. Two chemical experiments on a very large scale have been originated in the workshops of *La Ciotat*. 1200 square metres of sheet iron, covered with linseed oil, and mixed with minium for the first layer, and the same preparation, with the addition of mercuric sulphate (7.5 per cent.), for the second layer, have been launched on the sea; that is to say, that, endowed with a positive electrical polarity (for the hold itself is also painted with minium), this gigantic electrical pair, forming at the same time a kind of condenser, has been plunged into a solution of alkaline chlorides

saturated with air. It has then made two or three voyages to Brazil, touching successively at Lisbon, St. Vincent, Pernambuco, and Bahia, to go into port according to circumstances, either at Rio or Bordeaux. During these long voyages this hull, besides the friction of the water and the shock of the waves, has undergone great inequalities of temperature, which must have caused prodigious dilatations in its metallic sides.

We have now before us the results of these two experiments:—

1. A considerable quantity of oxides of iron (ferroso-ferric oxide predominating) either in concretions or pulverulent.

2. Ferrous chloride.

3. Plumbic chloride.

4. Metallic lead.

Chemical analysis has not hitherto enabled me to discover more than this, either in the concretions or bubbles, besides, of course, minium and the oily menstruum.

The following is the mean of ten analyses made by the same process and under the same conditions:—

	Concre- tions of the <i>Guienne</i> .	Concretions of <i>La Bearn</i> .
Sesquioxide of iron	72.45	70.54
Ferrous chloride	2.85	2.86

What has become of the mercuric sulphate? Hitherto I have failed to discover any traces of it. The transformation undergone by this salt by reason of the oil with which it is mixed, will be made the subject of another paper.—*Comptes-Rendus*.

On the Origin and Progress of the Phosphorus and Match Manufactures, by G. GORE.

(Continued from page 32.)

THIS wet and finely-divided substance having been dried, sifted, and packed in air-tight tins, is ready for sale.

It is well known in modern chemistry that a substance may exist in two or more physical states, possessing very different physical and chemical properties, and that there may be as great a difference in the properties of the same substance in its different states of aggregation as there is between two chemically different substances. For instance, there is as great an amount of physical difference between carbon as it exists in the diamond and as it exists in pure lamp-black as between copper and silver or silver and gold. The two kinds of phosphorus we have described are, then, precisely the same chemical substance, but in different states of aggregation. The following is a comparison of their properties. We will, for convenience, term them white and red phosphorus:—

White.	Red.
Poisonous.	Innocuous.
Evolves a strong odour.	Nearly odourless.
Phosphorescent—luminous in the dark.	Not phosphorescent—perfectly illuminous.
Melts at 108° F.	Melts at above 500° F.
Very transparent.	Opaque.

White.	Red.
Almost colourless.	Varies in colour from nearly black (with metallic lustre) to iron-gray, brick-red, crimson, and scarlet.
Freely soluble in various liquids.	Nearly insoluble in all liquids.
Distinctly crystalline.	Destitute of all crystalline structure (amorphous).
Soft, may be indented by the nail.	Hard as a common red brick.
Flexible as copper or lead.	Brittle as glass.

The great and most conspicuous fact is that red phosphorus may be kept in the dry state, exposed to the air, without inflaming; whilst the ordinary variety, under the same circumstances, quickly ignites. The minutest quantity of ordinary phosphorus in the red or amorphous variety can be detected by digesting the latter, in the state of powder, in bisulphide of carbon, and then letting fall a single drop of the clear liquid upon a saucer floating upon boiling water in a dark place; luminosity will immediately appear if white phosphorus is present.

There are several uses to which phosphorus has been applied, but, as far as quantity is concerned, almost the only important application is in the manufacture of lucifer matches. It is remarkable that, although the property of phosphorus of igniting by friction was known soon after its discovery, it was not until about the year 1833 that it was successfully applied to the manufacture of matches. It was then sold wholesale at four guineas a pound; in 1837, at two guineas; and at the present time, at less than half-a-crown. Manufactories of it exist in Great Britain, France (Lyons), Bavaria, Baden, Austria, and Sardinia.

Since the commencement of the manufacture of phosphorus upon a large scale in England, in 1845, the value of phosphorus imported into this country has regularly and rapidly decreased. According to the reports of the Great Exhibition of 1851, the value of phosphorus imported from all parts into Great Britain in 1844 was 2567*l.*, and in 1850 only 3*l.* And since that period it has become an article of constant export to the Continent and other parts, the proportion consumed in the United Kingdom being comparatively small. In his "Catechism of Agricultural Chemistry," Professor Johnston states that 200,000*lbs.* of phosphorus are consumed in London alone per annum. Persons conversant with the actual consumption know that at that time, and probably at the present hour, it would not exceed 20,000*lbs.*

It is also stated in a recent publication on Chemistry, by Professor Muspratt, (article "Phosphorus," p. 68*c.*) that phosphorus "is prepared as an article of manufacture in large quantity in London and Paris. Kane has calculated that in the latter city alone about 200,000 *lbs.* are yearly produced." There may have been once a very small production in London and Paris, but it has long since entirely ceased. The enormous consumption of fuel necessitates that, for an economic production, the manufactory be placed where coal is cheaply obtained; and the quantity of phosphorus produced in all France, at the date of Dr. Kane's book, is not likely to have been at all more than 20,000 *lbs.* It is plain that, by mistake, a cypher too many has been added.

Reserving a few remarks upon the importance of the labours of Brandt, Boyle, and others who investigated phosphorus, until the close of this article, I will now

give a brief account of the gradual development and present condition of the lucifer match manufacture.

The earliest recorded means of obtaining a light appears to have been by means of rubbing together two dry sticks. A hole having been made, by means of a sharp stone, in a dry piece of wood, and, by the same means, a piece of stick of different wood—laurel with ivy for instance—having been cut to a point at one end, the sharp point was inserted in the hollow, and rapid rotation imparted to it by means of the hands, similar to the motion of a chocolate stirrer, until, in a few minutes, the friction of the point generated sparks, from which a fire was obtained. Sulphured matches are also of very ancient origin.

The next method—that of the common flint and steel—was in use for centuries, and can even now be remembered by every adult person. It consisted in striking the edge of a small piece of flint against the edge of a rod of iron or hardened steel, in such a direction that the sparks which occurred fell upon pieces of tinder (charred linen), contained in a shallow tin vessel, and ignited them. By gently blowing the ignited tinder, the combustion spread and became sufficient to inflame a sulphured match. If the tinder was at all damp, it failed to ignite.

The discovery of phosphorus in 1669, with its luminous and igniting properties, at once indicated the possibility of using it to obtain a light; but no successful experiments of the kind at that period have been recorded. It was not until 1833 that it was successfully applied. In the meantime, a number of inventions for obtaining a light, some involving the use of phosphorus and others not, were adopted to a limited extent. Phosphoric tapers, consisting of ordinary wax tapers, with their wicks coated with phosphorus, and enclosed in air-tight glass tubes, were for some time in use. To obtain a light with them, the end of the glass tube was broken off, and the phosphorus, now exposed to the air, oxidised quickly and inflamed.

The next plan consisted of a well-corked bottle, coated internally with phosphorus; a sulphur match was introduced into it, and a little of the phosphorus adhering to the top of the match, caused the sulphur to inflame on coming into contact with the air. If it failed to ignite, the action was assisted by rubbing the match upon the cork of the bottle.

Homburg's pyrophorus, or fire-bearer, consisted of a dried and roasted mixture of three parts of alum and two parts of flour or sugar contained in a well-closed bottle. A little of this powder exposed to the air upon cotton wool ignited the cotton. This mixture contained no phosphorus. There were several other mixtures of a similar kind by Gay Lussac, Dr. Hare, and others, but they were only used by the curious and scientific.

The "inflammable air-lamp" of Volta consisted of a stout glass vessel containing zinc and diluted oil of vitriol. Hydrogen gas was generated by these substances, and on turning a cock the issuing jet of gas was ignited by an ingenious contrivance, consisting of an electrophorus, which passed an electric spark through it at the moment.

The "light syringe" consisted of a vertical brass cylinder and piston, with a small piece of tinder placed inside at the bottom and closed end. On compressing the piston very rapidly and with great force, heat was evolved by the condensation of the air and ignited the tinder, which was then removed by various contrivances.

In 1804, a little bottle, containing a mixture of phosphorus, oil, and wax came into use. A sulphur match

was dipped into the composition and then ignited by rubbing it upon the cork of the bottle. This was succeeded by a similar bottle of composition, with matches tipped with a mixture of sulphur and chlorate of potash.

In 1807, the "chemical matches," composed of sulphur matches tipped with a mixture of chlorate of potash, sugar, gum, vermilion, and sometimes camphor, were invented. They were ignited by dipping them into a bottle containing asbestos fibre moistened with sulphuric acid.

About the year 1820, Döberienner discovered that finely-divided platinum has the property of causing a mixture of oxygen and hydrogen gases to unite and inflame, and invented his well-known hydrogen lamp. This consisted of an apparatus somewhat similar to Volta's for generating hydrogen by means of zinc and diluted sulphuric acid in a strong glass vessel. On turning a small tap a jet of the gas issued forth and impinged upon a small ball of the platinum powder which immediately became red-hot and ignited it; from this a taper was lighted. By a peculiar mechanical contrivance in this apparatus, when the gas issued from the orifice, the acid and water came in contact with the zinc and generated a fresh supply of gas; and as soon as the tap was closed and a sufficient stock of the gas was produced, the liquid was expelled by the gas from contact with the zinc, and the generation of gas ceased.

In 1826 "lucifers," or light-bearing matches, were invented. They consisted of ordinary sulphur matches, tipped with a composition of chlorate of potash and sulphuret of antimony, and were ignited by drawing them briskly between folded glass-paper. The defect of these was that they required a considerable effort to ignite them, and the composition was apt to be torn off by the violence of the friction.

These were succeeded in 1828 by the "Prometheans," consisting of a small roll of gummed paper, containing at one end a dried paste of sugar, chlorate of potash, gum, and water, together with a small bulb of glass containing oil of vitriol. They were ignited by means of a small pair of pliers supplied with the box of matches.

In 1830, bottles, containing a mixture of one part of manganese and two parts of phosphorus, were patented for producing a light. Into these bottles common sulphur matches were dipped, and ignited by oxidation of the phosphorus on exposure to the air.

All these inventions failed in superseding the old-fashioned tinder-box with its flint and steel, chiefly on account of their greater expense, but also on account of their dangerous and uncertain action. About the year 1833 phosphorus was at last successfully introduced into match composition, and from that period the tinder-box rapidly declined in use, and the new matches became a successful and extensive branch of manufacture.

The phosphorus match did not, however, at once acquire the degree of perfection it now possesses. A variety of substances were tried in the preparation of the match-splints and in the composition of the inflammable paste: vegetable wax, bees' wax, sulphur, stearine, oil, and fat to make the wood ignite; glue, gum, and sugar to make the mixture adhere; chlorate of potash, saltpetre, sulphur, sulphuret of antimony, antimonial saffron, red lead, and peroxide of manganese to increase the combustibility; powders of charcoal, cork, pitch, resin, magnesia, lime, or chalk, to make the composition more porous; powdered glass, sand, or emery to increase the friction; and vermilion, red lead, red ochre, Prussian blue, smalts, ultramarine, or chromate of lead, as a colouring matter, and to disguise the other ingredients.

(To be continued.)

PHARMACY, TOXICOLOGY, &c.

Caffein as an Antidote to the Poisonous Effects of Opium.

Professor Henry Fraser Campbell, of Georgia, in the *Southern Medical and Surgical Journal*, publishes an article on this subject. After giving some account of caffein, and the use of coffee as an excitant, he describes the patient as a young man, 24 years old, who had, in a fit of mental depression, swallowed an ounce and a-half of laudanum, nearly an hour before his visit, 8 p.m. Narcotism had proceeded so far that emetics could not be employed; the muscles were greatly relaxed, the tongue falling back in the mouth and tending to stop respiration, and respiration exceedingly feeble. Cold water was applied to the head for a time, artificial respiration resorted to, and the stomach-pump then vigorously applied. At twelve o'clock the same night the case seemed more hopeless, respirations but four to the minute. Artificial respiration in a sitting posture was then resorted to, which seemed to have a temporary good effect. Dr. Campbell then thought of coffee, but the patient could not swallow, and he doubted the propriety of using the stomach tube in the then condition of the patient. Finding it difficult to get a strong infusion of coffee, the idea of employing caffein occurred, and having dissolved 20 grains in a quantity of infusion of coffee, it was administered as an injection by means of a syringe. In half-an-hour the respirations were eight per minute; an hour had not elapsed before he "forcibly jerked his left arm from the assistant," and told them "to let him alone." The narcotism slowly passed off, and at ten o'clock next day, when Dr. Campbell called, the patient had left the hotel and gone home. Although the effects of the narcotism were apparent for several days, they soon wore off, and the patient entirely recovered. Dr. Campbell believes that the caffein in this case was largely concerned in the recovery, and points to that alkaloid as probably possessing valuable antidotal powers in cases of narcotic poisoning from this drug.

On the Alkaloid and other Constituents of Coca Leaves, by Dr. A. NIEMANN.

THE inaugural dissertation of the author is published in *Wittstein's V. Schrift.*, ix. 489-524. It contains many interesting facts, but is too lengthy for translation; we therefore give in the following a condensed account of it.

After discussing the importance of the vegetable alkaloids in a medicinal point of view, and for the examination of crude drugs, the author disapproves of such incomplete investigations as enrich our knowledge with nothing else but names, and then considers the interest attached to those stimulating vegetables denominated by Von Bibra "narcotic victuals," like coffee, tea, cacao, and tobacco. The coca leaves are employed for similar purposes by the natives of Peru and Bolivia.

The Austrian frigate *Novara* brought from Lima a quantity of good coca leaves, which Professor Wöhler handed to the author for investigation.

After treating at length of the botanical characteristics of the order *Erythroxylaceæ*, which comprises only the genus *Erythroxylon*, and its geographical extension, he gives a minute description of *E. coca*, its culture, and the use and properties of its leaves, referring to the observations and opinions of Von Martius, Poeppig, Von Tschudi, Weddell, and Scherzer, some of whom have

advocated the introduction of the coca into the European navies and armies on account of its well-known qualities to preserve life and strength for a considerable time without food.

The author reviews the various incomplete investigations of Wackenroder, Johnston, Gaecke, and MacLagan, and states that the alkaloid prepared by Pizzi, of La Paz, and brought by Tschudi to Europe, was analysed by him and found to be gypsum.

The following is the author's process for preparing the alkaloid, which he proposes to name *cocaina*:—The leaves are exhausted with 85 per cent. alcohol, containing $\frac{1}{50}$ th sulphuric acid, the tincture treated with milk of lime, the filtrate neutralised with sulphuric acid, and the alcohol regained from the filtrate by distillation. The syrupy residue is treated with water to separate resin, the liquid is precipitated by carbonate of soda, when an odour reminding of nicotine is emitted, and the alkaloid is exhausted by repeated agitation with ether, distilling off most of the ether, and evaporating the residue spontaneously. The yield is about $\frac{1}{2}$ per cent of crude *cocaina*, consisting of colourless crystals mechanically mixed with a yellowish-brown matter, of a disagreeable, almost narcotic odour, which cannot be removed by animal charcoal or re-crystallisation, but may be separated by washing with cold alcohol. Less loss is sustained if the ethereal solution is agitated with diluted sulphuric acid, the aqueous solution of the sulphate precipitated by carbonate of soda, and the precipitate freed from the last traces of colouring matter by alcohol. The alkaloid crystallises best on evaporating spontaneously an alcoholic solution previously diluted with water.

Pure *cocaina* is in colourless, transparent, rather large prisms, inodorous, soluble in 704 parts water, at 12° C. (53.6° F.), more in alcohol, freely in ether. The solutions have an alkaline reaction, a bitterish taste, promote the flow of the saliva, and leave upon the tongue a peculiar numbness, followed by a sensation of cold. The crystals fuse at 98° C. (208° F.), and congeal again to a transparent mass, which gradually assumes a crystalline structure. Heated above its fusing point it becomes coloured and is decomposed. It runs up the sides of the vessel, and it is uncertain yet whether a small portion will sublime unaltered. It fuses upon platinum foil, and burns with a bright flame, leaving a charcoal, burning with some difficulty.

No physiological experiments have as yet been made with it.

The alkaloid is readily soluble in all diluted acids, forming salts which are of a more intensely bitter taste than uncombined *cocaina*. It absorbs dry hydrochloric acid gas, fuses and congeals to a grayish-white transparent mass, which crystallises after some days; the solution crystallises in long, tender, radiating crystals. The sulphate and nitrate dry to an amorphous, colourless mass, which gradually changes to crystals, the latter with great difficulty. The acetate readily assumes the form of a crystalline, sometimes herbaceous-looking mass.

The following is the behaviour of a diluted solution of the hydrochlorate to re-agents:—

Fixed alkalis: a white precipitate, slowly soluble in a large excess.

Ammonia and carbonate of ammonia: the same precipitate, readily soluble in excess.

Carbonate of soda: white precipitate, insoluble in excess, becoming crystalline.

Sulphocyanide of potassium: a slight turbidity.

Protochloride of tin: a white, curdy precipitate, soluble in much nitric acid.

Picric acid: a pulverulent, sulphur-yellow precipitate, becoming resinous.

Tetrachloride of gold, even in the most diluted solutions: a voluminous, light-yellow precipitate, becoming flocculent, soluble in the heated mother-liquor, and crystallising on cooling in beautiful yellow scales, resembling iodoform; it crystallises from hot alcohol in golden yellow scales or in a dense granular powder.

Bichloride of platinum: a dirty, grayish-yellow precipitate, becoming crystalline, soluble on heating, scarcely soluble in muriatic acid.

Tannin: a very slight turbidity; in the presence of muriatic acid a voluminous, pearly-white precipitate, shrinking and becoming resinous in appearance.

Bichloride of mercury: a voluminous, soon flocculent precipitate, soluble in muriatic acid and in chloride of ammonia. It does not crystallise from its solution in alcohol.

Iodo-hydrargyrate of potassium: a curdy-white precipitate, soluble in muriatic acid and chloride of ammonia.

Molybdate of ammonia in the most dilute solutions: a voluminous, yellowish-white precipitate.

Iodine: a kermes-brown precipitate.

Iodide of potassium: scarcely a faint turbidity; when containing iodine a strong brownish-red precipitate, which darkens gradually.

Tincture of iodine: no turbidity in the alcoholic solution of *cocaina*. No reactions were obtained with phosphate of soda, bicarbonate of potassa, tartar emetic, acetate and subacetate of lead, sesquichloride of iron, and iodic acid.

Cocaina is dissolved by fuming nitric and by concentrated nitric, hydrochloric, and sulphuric acids, without colouration; when heated, only the latter darkens and ultimately blackens it. A characteristic test with oxidising agents has not been observed. In its chemical and also physical properties, it resembles atropia to some extent.

The atomic weight of the alkaloid was determined from the double salt with chloride of gold, and was found from the amorphous compound = 283, crystallised from hot water = 280, crystallised from alcohol = 288. On heating the dry double salt, a sublimation of benzoic acid took place, the first observation of the kind of any known alkaloid. Ultimate analysis showed the following composition:—

I.		II.	Calculation.		
C	66.8	66.8	C	32	66.20
H	7.1	7.5	H	20	6.90
N	5.4	5.4	N	14	4.83
O	20.7	20.3	O	8	22.07
	100.0	100.0	C ₃₂ H ₂₀ NO ₈	290	100.00

Vegetable Wax from Coca Leaves.—The precipitate occasioned by milk of lime in the alcoholic tincture was treated with cold ether, which, on evaporation, left a soft, sticky, brown mass, wholly soluble in boiling alcohol, from which, on cooling, a white body was separated, appearing, after repeated solution in hot alcohol, as a snow-white, granular mass. It fuses at 70° C. (167° F.), is slowly soluble in hot alcohol, readily in ether, and is not acted on by solutions of alkalis or acids. By elementary analysis 80.2 C., 13.4 H., and 6.4 O. were obtained, which leads to the empirical formula, C₈₀H₅₂O₄. The composition of this body, called *coca wax* by the author, closely corresponds with that of Mulder's grass wax and syringa wax.

Cocainic Acid.—After precipitating the cocaina by carbonate of soda, as above, the dark red filtrate is freed from ether, neutralised by nitric acid, the sulphuric acid removed by nitrate of baryta, the excess of the latter by carbonate of ammonia, and the liquid neutralised by nitric acid; acetate of lead now produced a voluminous, dirty brownish-green precipitate, which was decomposed by sulphuretted hydrogen, and yielded a clear, yellowish-red solution, of slightly astringent taste, reddening litmus, and giving the following reactions:—Alkalies and their carbonates, a deep red colour; sesquichloride of iron, a dark-brownish yellow colour; glue and bichloride of mercury, no turbidity; the nitrates of mercury, dirty yellow precipitates, soluble in acids; tartar emetic, a flocculent, brownish-yellow precipitate; albumen, dirty yellow; acetate of baryta and lead, dirty yellow, soluble in acetic acid; terchloride of gold, dark brown precipitate, soon after a mirror of metallic gold; nitrate of silver, a turbidity, on heating a dirty yellow precipitate, afterwards a dark brown powder; hydrochlorate of cocaina, no turbidity. The tannin solution reduced chromate of potassa, and on boiling, also, Fehling's solution of copper; it dried on evaporation to a transparent brownish-red mass, containing some inorganic matter.

The filtrate from the precipitate with acetate of lead yielded with subacetate of lead, a yolk-yellow precipitate, apparently containing the same tannin, partly modified through the influence of the nitric acid.

Odeorous Principle.—On distilling 100 grammes of the leaves, a slightly turbid distillate was obtained, which, on re-distilling it with chloride of sodium, yielded white globular masses, lighter than water, and possessing the peculiar, tea-like, strong odour of the leaves. The quantity was insufficient for further analysis.

PHYSICAL SCIENCE.

Some Observations on the Sensibility of the Eye to Colour, by JOHN Z. LAURENCE, F.R.C.S., M.B. Lond., Surgeon to the South London Ophthalmic Hospital.

If, closing one eye—say the right—any highly luminous white ground, such as some portions of the sky on a sunny day, is viewed with the left through a dark tube, so as to exclude all extraneous light, after a little the eye will begin to feel fatigued, and a librating circular smoky spectrum will be perceived at the end of the tube. When the tube is laid aside and both eyes are directed to the sky, a similar spectrum will be observed, projected, as it were, on the surface of the heavens, but much darker. But if after a time each eye is alternately opened and closed, a rose-coloured spectrum is seen with the left eye, a pale-green one with the right. These appearances are seen still better if, instead of the sky, a white screen is used as the plane of projection in the second part of the experiment. At first an almost black circular disc is seen; this becomes lighter and lighter, till it is finally succeeded in the left eye by a bright rose-colour disc, surrounded by a violet border; in the right eye by an equally bright green, with a rose border. These spectra sometimes appear as if upon the surface

of the screen, sometimes, on the contrary, as if originating within the eyeball itself, and indeed may be even seen with both eyes closed. To see the above phenomena in all their intensity, a slightly different plan must be adopted. As the field of projection, a sheet of dead black paper in a dark room is to be used; the spectra then seen with either eye are the same, and their colours most splendid, both as regards brightness and tint. At first an emerald-green disc appears, surrounded by a narrow carmine, or, perhaps, more accurately, magenta border; the magenta tint is then seen to encroach more and more upon the green, till the whole disc is of the former colour, surrounded by a bluish-violet border; this last, in its turn, invades the magenta, till the final spectrum is of one uniform indigo-violet colour.

The above is the general sequence of colours which I, and other persons whom I have asked to perform the experiment, have observed; but these are liable to exceptions. Occasionally, the librating spectrum observed at the end of the tube in the first part of the experiment, acquires a faint rose, green, or violet tint. Sometimes, I have seen the spectra of the right and left eyes, in the second part of the experiment, reversed as regards colour.

These facts appear to prove the following propositions:—

1. That colour sensations may be excited in the retina, or brain, altogether independently of any external colour-stimulus.
2. That as an optical analysis of white light may be effected by a prism, so with the eye we possess the power of effecting, what may be called, its physiological analysis.
3. The last proposition tends to the conclusion that white light consists of three fundamental colours—magenta, emerald-green, and indigo-violet—corroborating in a remarkable manner the opinions of Professor Maxwell and Dr. Young on the same subject.
4. That a colour sensation excited in one eye is generally felt in the other, although this latter has not been exposed to the influence of light in any part of the experiment; that, in a word, a very close sympathy exists in the two retinæ, of which the consentaneous action of the two irides is probably but a reflex nervous consequence.

I may here allude to a distinction in ocular spectra, which has, I believe, not been taken much account of by observers of these phenomena. Some spectra seem as if projected on the plane to which we direct the eye, and in that case appear, as I have found from numerous measurements, linearly magnified in proportion to the distance of the eye from the plane of projection. Other spectra, on the contrary, are perceived, so to say, in the eyeball itself, and are of a subjective nature. Independent of the differences of their apparent seats, the two classes of spectra present certain other well-defined distinctions. Projected spectra are only perceived with the eyes open, and are generally but faint in colour; while subjective ones may be seen with the eyes shut, and are always intense in colour. At the same time I am disposed to ascribe the differences of colour, in a certain degree, to the diluting influence of extraneous light; for projected spectra are always seen more vivid in a dark room than in daylight.

The green spectrum observed on a sheet of white paper, after prolonged contemplation of a red wafer, has been commonly explained thus—"When the eye has been for some time fixed on the red wafer, the part of

¹ Since writing this paper, my attention has been directed to a series of elaborate disquisitions by Brücke and Fehner in Poggendorff's *Annalen der Physik u. Chemie*, vols. lxxxiv., 1., and xlv., to which I beg to refer my readers.

the retina occupied by the red image is deadened by its continued action, and insensible to the red rays which form part of the white light from the paper; consequently will see the paper of that colour which arises from all the rays in the white light of the paper, but the red; that is, of a bluish-green colour, which is therefore the true complementary colour of the red wafer."³

That this explanation is not correct seems to me to be proved by the following experiment:—

I, at night, made a room (which is provided with thick American-leather blinds for ophthalmoscopic purposes), to all appearances, absolutely dark, then viewed with the left eye a small aperture in a dark box, covered with a piece of emerald-green glass, behind which was the nearly white flame of a lamp. The right eye was kept closed, and covered with a thick handkerchief. After a time I blew out the light in the box, and looked at a screen covered with a sheet of dead-black paper. With the left eye a large carmine-coloured projected spectrum of the flame could be seen; with the right eye I generally perceived no spectrum at all, or if any, but of a very faint tint. But, if the latter eye was exposed to a white light during the first part of the experiment, I invariably perceived the same spectrum with this eye as I did with the left one.

This experiment shows that the presence of white light is not necessary for the perception of complementary ocular spectra, and further would appear to indicate that for a sympathetic spectrum to be excited in the eye which has not been exposed to the colour-stimulus, the excitation of some light is necessary.

M. Plateau painted one half of a piece of paper red, the other green; and after alternately directing the eyes to each half, covered them with a handkerchief, and observed a black image, having on each side a complementary coloured image.⁴ He hence inferred that "the combination of accidental colours produces black." Sir D. Brewster very properly objects to this conclusion, "because the eye has been in succession rendered insensible to the two colours which compose white light itself."⁴ Elsewhere the same author says, "If we take the two complementary colours, namely, the red and the green tints forming the ordinary and extraordinary pencils in the polarised ring, which, by overlapping, form white light, then it is manifest that the accidental colour of the overlapping part is black, and hence the sum of the action of the red and green acting separately must also be black."⁵

Notwithstanding, however, the authority of Sir D. Brewster, the following experiment which I have performed appears to me rather to corroborate Plateau's view. If the two halves of a card painted red and green respectively, be illuminated by a green or red light, they appear black. In the same way, but depending on a different cause, the two halves of the card, if viewed through green or red glass, appear black.

Another set of observations, connected in a degree with the preceding, may be here noticed. Chevreul⁶ distinguishes two chief species of contrast of colours, simultaneous and successive contrasts. But an examination of these distinctions shows them in my judgment to be more apparent than real, and but the expression of

one fundamental fact, viz., that the eye on perceiving any one colour acquires a tendency to see its complementary. Thus, to take an example of Chevreul's simultaneous contrast:—If a strip of red and one of yellow paper be viewed side by side, near the line of contact, the red paper inclines to violet, the yellow to green. The rationale of this is at once obvious: the red mingling with the complementary of yellow, i.e., blue, produces the violet tint; whilst the yellow mingling with the complementary of red, i.e., green, produces a light green; and this same law holds good in the juxtaposition of any two colours whatever. By the term successive contrast, Chevreul designates the familiar phenomena of complementary ocular spectra, of which a most comprehensive history has been given by Darwin, in the *Philosophical Transactions*, vol. lxxvi. p. 33, *et seq.* Du Tour⁷ thought that the two eyes cannot perceive each a separate colour at once. He says that if, e.g., a blue disc be presented to one eye and a yellow one to the other, the result is that the mind perceives alternately the one or the other colour, but not the two at once. But I would submit that these two statements do not include the whole facts of the case. I took two tubes, each 10½ inches long, and applying the end of one to each eye, viewed the sky through them. I found that when the contiguous edges of the tubes at their further ends were some inches apart, two distinct white circles of sky were seen; these circles touched when the edges of the tubes were from 2½ to 2⅝ inches apart, and, when closer, the two circles appeared as one. If now the further end of one tube was covered with a piece of green glass, the end of the other with a piece of red, as long as the ends of the tubes were kept not closer than 2½ to 2⅝ inches asunder, the two coloured discs were perceived perfectly distinct from one another; no alternation of either colour to the exclusion of the other, as in Du Tour's experiment, ensued, so long as the tubes were inclined to each at this or any greater degree of divergence.

Another very interesting series of phenomena depending on the intrinsic sensibility of the eye to the impressions of colours are those of coloured shadows. The first exact observations on these were made by Count Rumford.⁸ He observed that the two shadows of an object placed in front of a white ground, from a white and a coloured light, were of the two colours complementary to the latter. I have investigated this fact a little more closely. The method adopted has been to throw a white and a coloured (red) circle of light from two magic lanterns on a white screen, before which a slender wooden rod was placed. It is easy to satisfy ourselves that the red shadow is produced by the (otherwise colourless) shadow cast from the interception of the white light being simply illuminated by the other red light. The green shadow is the shadow produced by the interception of the red light, illuminated by the white light. These coloured shadows have, by Rumford and many subsequent observers, been ascribed to the effect of contrast. But this appears an inadequate explanation; for if, with one magic lantern, a half-white and a half-red circle of light be thrown on a screen, a shadow thrown across the two fields is simply dark, without any colour at all. If, again, a red and a white disc of light be thrown from two magic lanterns respectively on a screen, so as partially to overlap, where the overlapping

takes place two complementary shadows of any object are seen, but in the other two parts of the field only one colourless dark shadow is seen.

The following facts seem to form the basis of the explanation of coloured shadows:—Firstly, the experiment of Rumford,⁹ that a piece of gray paper placed next to a piece of coloured paper, both on a black ground, with the exclusion of extraneous light, appears tinged with the complementary colour. Secondly, I found by my own experiments that if, in a dark room, the screen is illuminated with a red circle of light from a magic lantern, the greenness of the shadow and the redness of the ground on which it appears are inversely proportional to one another. By approximating the red light to the screen this becomes redder, whilst the shadow of the rod placed before it becomes less green and darker, till it becomes an ordinary black shadow; that, on the other hand, removing the red light till it leaves the white screen but faintly tinged with red, brings out the green shadow very prominently, and on admission of light into the room, a second faint red shadow comes out.

Meusnier observed, "that when the sun shone through a hole a quarter of an inch in diameter on a red curtain, the image of the luminous spot was green." Another observer, Mr. Smith, of Fochabers,¹⁰ states, "If we hold a narrow strip of white paper vertically, about a foot from the eye, and fix both eyes upon an object at some distance beyond it, so as to see it double, then if we allow the light of the sun, or a light from a candle, to act strongly upon the right eye without affecting the left, which may be easily protected from its influence, the left hand strip of paper will be seen of a bright green colour, and the right hand strip of a red colour."

From all these facts, I think the conclusion arrived at by Sir David Brewster appears highly probable, that "as in acoustics, where every fundamental sound is actually accompanied with its harmonic sound, so in the impressions of light, the sensation of one colour is accompanied by a weaker sensation of its accidental or harmonic colour."¹¹ To this might perhaps be added that there is a tendency in the eye to, as it were, decompose white light into two complementary colours; and, further, that the predominant decomposition is into red and green.

Applying this theory to the phenomena of coloured (e. g., red and green) shadows, the red shadow has already been shown to be simply due to the illumination of a colourless shadow by a red light; whilst, on the whole of the rest of the field of the white screen, the red tint cast from the magic lantern is sufficiently powerful to overcome the green tint which the eye would otherwise perceive, excepting at one spot,—namely, that which does not receive any red light on account of the interposition of the opaque rod. Here the green (harmonic) colour, having no antagonistic red to overcome it, is rendered sensible to the eye.

An Old Cathartic Revived.—The leaves of the *Globularia Alyssum*, which were known in the middle ages as a purgative, have been recently re-introduced by Dr. Planchon, of Montpellier, who claims for them that they are efficient as a purgative, without producing nausea or griping, and that their bitter properties give them a tonic action.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Saturday, March 16, 1861.

A Course of Ten Lectures on Inorganic Chemistry, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

LECTURE IX.

HAVING considered in our previous Lectures the principal properties of the elements oxygen, hydrogen, nitrogen, and carbon, and of their chief compounds, we are now in a position to make ourselves acquainted with the atmosphere surrounding our globe, and I intend to devote the present Lecture to some statements with regard to this, to us very important, mass of gaseous matter. The atmosphere consists of a mixture of gaseous, vaporous, liquid, and even solid matters. But the two latter may be regarded as abnormal, and, consequently, we may confine ourselves to the gaseous constituents of this envelope of our globe. Just as the ocean may be presumed to contain a little of everything that is soluble, so we may with equal propriety assume that the atmosphere contains a little of everything that is volatile; but the quantities of most of these substances are so infinitesimally small, that they entirely elude all our attempts even to detect them; nevertheless, even such very unærial matters as potash, lime, magnesia, iron, and manganese, have been found in the air in very minute quantities under particular circumstances. Since the experiments of Faraday, which have proved that there is a limit of temperature, below which the less volatile substances do not form vapour, we cannot now assume that these solid bodies to which I have just referred are present in the air in the form of gases or vapours; they must be present there in a solid form, and that such solid bodies really do exist in the atmosphere, and are a long time suspended in the air, there can be no doubt. Every sun-beam that passes through a room shows us an infinite number of these very particles hovering in the air. You know if a sun-beam should pass through an opening in a shutter at one end of a room and out of another opening at another side of the room it ought not to illuminate the apartment at all; but the fact is, that it does illuminate it, and that you see the path of the beam through it. Every time a beam of electric light passes through this theatre you see the track of the light—the direction in which it goes,—by means of these little particles reflecting the light and rendering themselves in this way visible. I think it will not be impossible for me to render visible to you the presence of solid particles in the air—particles of matter which cannot really be volatile, which only exist there, in fact, in a state of mechanical suspension,—by means of this nearly colourless gas flame. If you notice it attentively, you will see that there are little yellow particles in it. These yellow particles are due to the presence of common salt in the atmosphere, the little particles of which entering the flame, are there ignited, and communicate the intense yellow colour which each particle is seen to produce when it passes through the flame. Here we have some chloride of sodium. I will simply rub it in this mortar, and then agitate it a little, in order to throw the particles into the air. I dare say the effect will not take place immediately, but if you watch the flame for some little time after I have agitated this chloride of sodium, you will see that those little yellow particles already floating in the room before we commenced the experiment will be greatly increased in number. There are some of them distinctly visible, although the flame is at a great height above the mortar. This proves that these little particles of chloride of sodium, although so many hundred times heavier than the air, still continue to float in the atmosphere, by virtue of their very minute

division, and consequently we can have even permanently solid matters present in the air, just as such matters as gold, for instance, can be suspended for months, or even for years, in water, without sinking to the bottom. If the gold be finely enough divided, it requires months, sometimes it requires even years, to subside through the space of two or three inches of water.

Our atmosphere, as you are aware, extends to a height of some forty-five miles from the surface of the earth, but such is the varying density of the air that when you have risen to the height of three miles in the atmosphere, you have then about one-half of the total weight of the air below you. At that height you might draw a line through the atmosphere which would contain one-half of the atmosphere below it, and one-half above it. Although we generally regard the air as an exceedingly light material, still its absolute weight is far from inconsiderable. I might show you that even a small flask of it contains enough to be very appreciable to a balance of moderate delicacy. It is 815 times lighter than water, and more than 11,000 times lighter than mercury, still, if you conceive a column of atmospheric air extending from this table upwards to the extreme limits of the atmosphere, and measuring only an inch square, that column of air weighs fifteen pounds. A moderate sized room contains sufficient air to crush a man to death if it could be collected together and placed upon him, and this theatre contains considerably more than one ton of atmospheric air. Therefore, you see, although we almost forget its presence around us, still this gaseous envelope of our globe possesses a very considerable absolute weight.

The composition of the atmosphere has for many years engaged the attention of chemists. The first experiments that were made upon the composition of air after it had been ascertained that it consisted chiefly of two gases, namely, nitrogen and oxygen, led to the inference that its components were liable to very considerable variations. It was found that sometimes there was 18 per cent. of oxygen, at other times 19 per cent., at other times 20, and at another time 24 or 25 per cent. of oxygen; and it was imagined that the salubrity or otherwise of any district depended upon the amount of oxygen contained in the air of that district. But these apparent differences in the composition of the atmosphere were due entirely to the defects of the modes of experiment at that time. The modes of estimating the quantity of nitrogen in the air were so defective as to give rise to errors as serious as those to which I have alluded. When this process of analysis became further perfected, the opposite error was fallen into for a short time, and the indications of this more perfect method showed a complete uniformity in the composition of atmospheric air. Specimens of air taken from crowded cities, from the country, and from great heights, were all perfectly uniform in composition. As the methods of analysis, however, still further improved, the incorrectness of this conclusion was also discovered, and it was found that there are variations in the composition of the atmosphere—variations, it is true, within very small limits, indeed, but still far within the reach of experiment to detect. The extent of these variations, and the composition of the air itself taken from different localities, you will see on one of the diagrams before you. Before referring to that, however, perhaps it will be better that I should direct your attention to this table, containing the normal constituents of air in 100 volumes:—

100 volumes contain	
Oxygen	20.61 volumes
Nitrogen	77.95 "
Carbonic acid	.04 "
Aqueous vapour	1.40 "
Nitric acid, ammonia, and fire-damp	Traces
100.00	

The first four are the only substances in the air which are capable of exact estimation. Attempts have been made to estimate the ammonia, and probably we have come within a very small fraction of the truth; but we may represent the remaining constituents—nitric acid, ammonia, and fire-damp—by the term "traces," which a chemist usually applies to a quantity of matter so small as to be practically incapable of accurate determination by experiment; the quantities of these materials are so infinitesimally small that they bear scarcely any appreciable relation to the other constituents. Now, you will see that, of these four principal constituents two of them, namely, nitrogen and oxygen, constitute nearly the entire bulk of the air; and if you extract from the atmosphere the aqueous vapour and the carbonic acid, then you have left the oxygen and nitrogen in the proportions indicated in this second table, which contains the results of an extensive series of analyses. It shows you the per-centages of oxygen and nitrogen contained in air that has had its carbonic acid and water (or aqueous vapour) removed from it. There are the results of two analyses of air in nearly every case. Here are two analyses of atmospheric air at St. Bartholomew's Hospital; the two lines of figures represent the two different examinations, and show that the errors of analysis fall within a very small variation. You will see also, from an inspection of the table, that there really is a variation in the composition of air when taken from different localities.

Composition of Atmospheric Air from various Localities.

	20.882	77.117

Some of these specimens were taken during a voyage from Liverpool to Vera Cruz; and another in a balloon at a height 18,000 feet above London. The specimen taken at Algiers in 1851, may be regarded as furnishing, what we may term, the first abnormal result; it contains, you see, a comparatively small proportion of oxygen. Our averages have been something like 20.9 of oxygen, but this at Algiers contained only 20.420, or, as determined by the second experiment, only 20.395 of oxygen. You see the two experiments agree very nearly, so that there can be no doubt whatever of the correctness of the two analyses. The analysis of the air of the Ganges was taken at the time when a very violent attack of cholera was breaking out. All the other examples give us almost precisely the same average; and there can be but little doubt that air collected at Algiers and in the Bay of Bengal and on the Ganges would, if examined carefully at the present time, be found to possess also the same composition as the other specimens; but the presence of organic matter in these specimens prevented an accurate determination of the oxygen; in fact, it was noted in the case of the air upon the Ganges, that there were organic emanations proceeding from the river; there was a dense vapour over the river and a very perceptible odour of organic matter in the air. Now, what would be the effect of this organic matter? The effect would be this—that in the analysis of the air, the organic matter would diminish the quantity of oxygen as determined by means of combustion with hydrogen which is the best, and in fact the only correct mode of determining the quantity of oxygen contained in the air. The presence of organic matter would have the effect of reducing the apparent amount of oxygen, and thus the abnormal result would be obtained with the same kind of analysis which was performed upon the other samples. They were all analysed by substantially the same process; but in the case of the air containing these abnormal quantities of organic matter, the amount of oxygen indicated by experiment would be smaller than that actually contained in the air at the time; and there is very little doubt in my own mind that the abnormal results of the examination of these three samples of air are due to this cause—the presence of organic matter.

The mode of estimating the oxygen in atmospheric air is very simple,—at least one of the modes of doing it; and I think I shall be able, in the course of a single minute, or little more, to make the experiment before you.

Here is a tube graduated into 100 divisions with decimals. These divisions are not, of course, large enough to be seen at a distance; but I have no doubt we shall see the proportion of the oxygen due to its absorption by the re-agent we shall use to remove it. In all these gaseous analyses it is necessary that the gas, both before and after the application of the re-agent, and before each determination of gaseous volume, should be brought to one uniform temperature and pressure; and this we do in the present instance, as nearly as possible, by immersing the whole apparatus in this vessel of water, which maintains during the whole course of the experiment almost a uniform temperature. Now I think we have got the right quantity of air. The water contained in the lower limb of this endiometer prevents communication between the internal air or gas contained in the tube and the external atmosphere. In reading the volume I bring the two liquids—that is the water outside and that inside the tube—to the same level. Now we have almost exactly 100 volumes of air in this tube. From this liquid in the open limb of the tube I remove a certain quantity by depressing this glass tube open at both ends, and taking out each time a little of the water; and now I am going to pour into it a quantity of caustic potash, which will, of course, have the effect of removing the carbonic acid contained in the air; and we might also, if we could afford the time, determine the amount of carbonic acid contained in this sample of air,

by the agitation of the air with this caustic potash; but the absorption would be so trifling, that it is almost impossible to get the result by an experiment of this kind. It is only the oxygen that can be estimated in this way; the carbonic acid, as you have seen from the table, is so minute in quantity, that we may in fact, in this experiment, disregard it altogether, and assume that the air we are operating upon is free from carbonic acid. I am now going to put into the tube some pyrogallate of potash and pyrogallallic acid, which has the property of absorbing oxygen with very great rapidity. I have mixed these two solutions, and I will agitate them with a quantity of the air in this tube. You will notice that this solution of pyrogallate of potash, which was first colourless, has become of an intensely red colour, and in the course of a few minutes it will, I dare say, become so dark that it will appear to you almost black. This colour is due to the product of oxidation of the pyrogallallic acid, which oxidation takes place at the expense of the oxygen of the air contained in the tube. In this way, by a few minutes' agitation, the whole of the oxygen is removed, and at the same time of course the carbonic acid is removed too; but the latter being in such small quantity we may, as I have said, neglect it altogether. Now, when we allow the liquid to subside here, and you will then observe that there will at once be a rise of the liquid in the tube. [The extremity of the tube was accordingly inserted in the water as described.] You see it has now risen to about this point [pointing out the level of water on the scale of the endiometer]. We have, in fact, absorbed the oxygen; and now if we restore our temperature to its original normal condition by immersing the apparatus in this vessel of water, we shall be able to read the volume of gas, which will be, of course, the original volume of air we took minus the quantity of oxygen which has been absorbed by that pyrogallate of potash. The temperature is now adjusted by immersion in the water, and the tube brought to the same position as at the commencement of the operation. We have now about 20.4; the liquid has risen between 20.4 and 20.5 in this tube. Now, this, for a rough experiment, is sufficiently near perhaps for our purpose. It ought to have risen 20.9 volumes. If we had time to regulate the temperature and the pressure, and to make our observations with the leisure with which one can make them in a laboratory, we should have obtained by this means very nearly the result of exploding atmospheric air with an excess of hydrogen—40.8 or 20.9 per cent. of oxygen.

Now, we have thus demonstrated the presence of oxygen; and the presence of nitrogen we have demonstrated in a previous Lecture, for you will recollect we prepared our nitrogen in one experiment by burning away the oxygen of the air, when we found that the residue was nitrogen. The presence of aqueous vapour, or moisture, in the air is also very easy of demonstration. Here, for instance, we have had a freezing mixture suspended in this room for some length of time, and it has cooled the outside of this vessel considerably below the freezing point; and you see the moisture contained in the air of this room has crystallized as ice, or hoar frost, upon the outside of this cone of tin. If we allow the vessel to stand until the close of the Lecture, I dare say we shall have some few drops of water, collected from the air, dropping from the end of the cone; in fact, we have on the cone already a few drops of water from the condensation of the aqueous vapour of the atmosphere. Most of it is congealed, and is in a solid form. It will require some little time yet for the temperature of the vessel to rise sufficiently high to melt ice. There is, however, another mode here by which we can illustrate the presence of moisture in the air. We will reread a quantity of air which contains moisture, or is nearly saturated with moisture. The temperature of the air under all circum-

stances where it is rarefied, by being pumped out of a receiver in this way, will fall; and air cannot contain so much moisture at a low as at a high temperature. Therefore, if we rarefy the air in the receiver, that air being saturated with moisture will deposit a quantity of moisture in the receiver, on account of the cold produced by the rarefaction; and you will see a cloud within the receiver. This cloud is due to the moisture deposited in the form of very minute drops within the receiver. [The air-pump was worked, and a cloud of moisture was seen within the glass receiver.] You see the glass is now comparatively dim; and there is a kind of cloud or vapour within the receiver. This moisture present in the air is estimated by various instruments which are termed hygrometers. Here is one of them which is that most generally used—Daniell's hygrometer, which consists of two bulbs connected by a glass tube. They contain ether; and as we pour ether upon the outside of one of these bulbs it reduces the temperature even of the other bulb, and the moisture of the atmosphere is deposited upon the black bulb just as it was deposited here upon this tin cone. The operation is watched until that moisture is just beginning to deposit upon the black bulb, and then the temperature of the thermometer in the interior of the bulb is noticed, and we know that the moment when that moisture is deposited upon the bulb, the air at that particular temperature is just saturated with moisture; we further know what amount of moisture is necessary to saturate the air at a particular temperature, as we have already made experiments on this subject. We are thus able to tell from the indications of this instrument the quantity of moisture contained in the air at the time the experiment is made. This table, representing the possible amount of aqueous vapour contained in 100 volumes of atmospheric air at various temperatures, gives us at once that result in per-centage quantities as determined by this instrument.

Temperature F.	Per-centage of Aqueous Vapour	Temperature F.	Per-centage of Aqueous Vapour
0	0.1	47	1.1
10	0.2	50	1.2
20	0.3	52	1.3
25	0.4	54	1.4
29	0.5	56	1.5
32	0.6	58	1.6
35	0.7	59	1.7
38	0.8	60	1.8
41	0.9	70	2.4
44	1.0	80	3.5

If we found, for instance, that we required to reduce the temperature to the zero of Fahrenheit's scale in order to get moisture deposited, we should know then that we had $\frac{1}{10}$ th of a volume present in 100 volumes. If we reduce the temperature to 10° before the moisture was deposited, we should know that we had $\frac{2}{10}$ ths of a volume present in 100 volumes of air. Thus air at these particular temperatures may contain any amount of aqueous vapour below that in the table, but it cannot possibly contain any amount above the quantity stated there. When the temperature falls below these points, then the vapour is deposited and becomes visible in the form of dew, or rain, or some precipitation of that kind.

The presence of carbonic acid in the air is very readily demonstrated by exposing lime-water, our delicate test for this gas, freely to the atmosphere. Here is a vessel containing lime-water which has been exposed for some hours, and you see it is covered with a film of considerable thickness of carbonate of lime, due to the absorption of carbonic acid from the air.

(To be continued.)

NOTICES OF BOOKS.

A Practical Treatise on Coal, Petroleum, and other Distilled Oils. By ABRAHAM GESNER, M.D., F.G.S., Consulting Chemist, Author of "Industrial Resources," "History of New Brunswick," "Geological Reports," &c., &c. New York: Baillière Brothers, 440, Broadway.

It is now some time since we noticed a kindred work by Dr. Antisell—kindred not only in subject but in treatment. Certainly Dr. Gesner's book has the advantage of being correct so long as its author speaks of what he knows. Dr. Gesner is doubtless a good practical coal distiller, but, scientifically speaking, a poor chemist. We doubt not that he has stood by and directed many hundreds of distillations, and that he has prepared thousands of gallons of his favourite kerosene. Why, then, does he not write solely on practical subjects? and why does he injure his reputation, and bring ridicule upon his book, by an affectation of knowledge upon points where his information is most limited. Dr. Gesner, it is true, surpasses Antisell in his practical knowledge, but, unhappily, he also surpasses him in his blunders. In fact, it would be difficult for any good student of a chemical class to accumulate so many in so short a space. Dr. Gesner's great source of scientific information is the late lamented Dr. Gregory's excellent "Handbook of Organic Chemistry." He has not even obtained the last edition, but has rested satisfied with that of 1852. But, in order to give a fair outline of his book, we will discuss some of his chapters *seriatim*.

Chapter I. is chiefly occupied with a sketch of the history of coal distilling. It is exceedingly brief, but perhaps sufficient, and what is there is written with candour. The descriptions of the varieties of coal, and the results of their analysis, are also extremely brief. The first glaring blunder which attracted our notice is on page 14. The Author, describing the metamorphosis undergone by plants during their conversion into coal, says:—"The changes that have taken place in the original plants during their passage from woody fibre into coal are ascribed to the evolution of a part of their carbon, hydrogen, and oxygen, as there is less of those elements in the coal than in wood." The Author, instead of writing "those elements," should have said less *hydrogen and oxygen*, because coal, as everyone knows, contains far more carbon than wood. A ridiculous passage also occurs on page 16, whether originally due to the printer or Author we cannot tell. Certainly, however, the Author is responsible for permitting such mistakes to pass in the press proofs. Alluding to the pyrogenous derivatives of organic acids, he says:—"Organic acids distilled with strong bases part with the elements of carbonic acid, which uniting with the base and the acid, minus the carbonic acid, comes over in the form of a new product." The passage is in every way inadequate to tell the true story of the formation of ketones, &c. An approach to sense might, however, have been made by writing and punctuating the passage thus:—"Organic acids distilled with strong bases, part with the elements of carbonic acid, which unites with the base; and the acid, minus the carbonic acid, comes over in the form of a new product."

Chapter II. (on the materials employed for the production of oils) is valuable to the coal and tar distiller, and contains much practical information. It is interesting from its allusions to the oil wells which are now attracting so much attention in America.

Chapter III. is on the nature of the products obtained from bituminous substances, and on the apparatus used in distilling. Several stills and ovens are described with their condensers, &c., and the descriptions are practical and tolerably well up to the present state of coal and tar distilling.

Chapter IV. is devoted to the products of the distillation

of wood, coals, asphaltum, bitumen, petroleum, and other substances capable of yielding oils. The Author, like so many of his brother writers on chemistry in America, cannot spell. Capnomor with him is copnomor; pittacal is pittical; aniline is analine; ampeline is ampaline; rosolic is rosalic; carbazotic is carbozotic; St. Evre is St. Evrre; margarie is margonic; basic acid is made into the paradox basic acid. (See pages 36, 58, 59, 60, 62, 64, 68, 69, 75, 79, 80, &c.) The proof that the errors alluded to are not misprints, is found in the fact of their continual repetition. The Author, in his wretched description of eupion, states that "With nitric acid it forms several new combinations analogous to those of benzole," and that it "Does not exist ready formed in the tars, but is produced by the action of strong acids and alkalies upon the distillates of crude oils." Both these statements are hopelessly incorrect. The little that the Author writes about eupion that is his own, is incorrect, and what he borrows from Dr. Gregory, which includes the chief portion, is taken from an old edition of his work published before the true nature of eupion was made out.

The Author is, we need scarcely say, entirely unacquainted with the modern researches on the nature of the eupion, &c., from Boghead coal.

The Author is fond of dragging in quotations from Dr. Gregory about homologous series, and yet that he is entirely ignorant of their true value in science, is evident from the fact that his lists of homologous bases and hydrocarbons are never correctly written. In a list of "The oily substances obtained by the distillation of coal-tar," cumole is put before toluole; and, among other errors in the list of bases, parvoline is put before lutidine, and the formula of the latter is written C_9H_7N , instead of $C^{14}H^9N$; moreover, pyridine, the first and principal base of the series, is altogether omitted. The same remark applies to lepidine and cryptidine. The Author's judgment is scarcely shown by leaving his tables in the state indicated, and instantly rushing, in the most uncalled-for manner, into an enumeration of the chlorinated and brominated substitution derivatives of naphthaline and aniline, which, with great presumption, considering his evident extreme ignorance of the subject he calls "uncertain combinations."—P. 63.

At page 64 carboxotic acid (*sic*) is one moment called Welter's bitter, and the next, the discovery of it is attributed to M. Guinon, of Lyons, and its formula is given $C_{12}H_2N.O_4O_2$! Would it be believed that after these painful displays of ignorance the Author devotes his next Chapter (V.) to an account of homologous series, with a sketch, copied from Regnault, of the so-called law of atomic weights, being multiples of that of hydrogen; immediately after which, he drags in Dr. Gregory's excellent sketch of the theory of types, but as he commences with the words, "A series of types has therefore been discovered," becomes absolute nonsense, following as it does the quotation from Regnault. It would be of no use to pursue the subject further. Dr. Gesner is probably a very good tar distiller, and may make excellent kerosene (or whatever he chooses to call the fluid known in this country as photogene or paraffine oil); but he is so deficient in his organic chemistry that the best advice we can give him is, to purchase the last edition of his favourite work, and read it carefully before attempting to teach others. It is only fair to mention that the descriptions of the methods of preparing photogene are tolerably clear and practical.

NOTICES OF PATENTS.

Obtaining Pulp for the Manufacture of Paper from Indian Corn. H. DOFFENNES, Brussels. (Not proceeded with.)
For the production of a pulp suitable for paper-making, the inventor subjects the waste portions of maize, or Indian

corn to certain mechanical processes for the purpose of disintegrating the cellular tissue, and to an after chemical treatment, whereby the plant is divested of small quantities of colouring and extractive matters. The vegetable cellulose prepared in this manner is made to furnish a material like pulp, ready for conversion into paper by the ordinary processes of manufacture. The specification directs that the maize stalks and heads, and in the case of damaged corn, the grain also, be chopped into small pieces in a chaff-cutting machine, then threshed, to remove the sand and earthy impurities. The matters thus purified are washed and pulped in any suitable apparatus, first with water alone and then with soda, again washed with water, and, finally, bleached by the action of chlorine. The white pulp ultimately produced is said to furnish excellent paper.

The failure of this British patent may very possibly be attributable to the want of raw material. In the South of Europe, where maize is more abundantly cultivated, the process would, doubtless, be capable of great results. The modes of treatment, both chemical and mechanical, appear well adapted to the production of a serviceable pulp from maize if only the supply could be obtained.

Manufacture of Colouring Matters and Pigments from Coal-oil, Raw Naphthaline, and from the Waste Lime from Gas-works. L. C. E. VIAL, Paris. (Not proceeded with.)

THIS invention relates to the production of a red colouring matter from crude naphthaline or coal-tar oil, under the combined influence of an alkaline base and of atmospheric oxygen. To purify it from certain associated matters, the coloured principle is dissolved out by treatment with carbonate of soda, and re-precipitated from this solution by acetic or a cheaper mineral acid. The specification describes also a process for obtaining a green or bluish colour from the lime waste which has been employed for the purification of gas. It consists merely in a simple treatment with nitric acid, when the material is precipitated as a deep green or bluish colour, which requires only to be washed to render it fit for use.

Apart from the consideration of expense incident to all processes wherein large amounts of nitric acid would have to be employed, a manufacture based upon the action of acid on products so innately offensive as the "blue Billy" of the gas-works would require to be conducted in remote localities; and, even this point overcome, there will be, according to the showing of the specification, uncertainty in regard to the tint of colour ultimately produced.

CORRESPONDENCE.

Dyeing Magenta.

To the Editor of the CHEMICAL NEWS.

SIR,—Perhaps you will do me the favour to insert the following reply to "Magenta," *alias* "Mares-nest," and as I do not intend to trouble you again on this subject, I hope this will at once remove unfavourable impressions from the minds of gentlemen who manufacture articles which fail to meet with that general approval from practical men which was anticipated, and hope such gentlemen will in future search into the practical objections before publishing to the world assertions that dyers object to use an article simply because it is given to them in a powder.

It is a well-known fact that dyers have suffered, both in pocket and character, by repeated attempts to use the powder, and such other solutions as could be obtained, and after obtaining results with them quite unsatisfactory, they have been compelled to keep goods weeks, instead of days, at no small inconvenience, till they could obtain

some of the well-known makes of solutions, which at one time commanded almost fabulous prices.

I will now lay before you the method most approved by practical men to produce a magenta on Cobourgs, Orleans, &c. After the goods have been properly scoured to remove all foreign matter, the hot-bath is prepared by adding sufficient colouring to produce the colour required, the quantity of hot water being regulated by the amount of cloth to be dyed. The goods are then worked in the bath at about 180 F., till the colour has got even upon the cloth. The cloth is then taken out and washed in cold water, when it will be found that the worsted only has received the dye, the cotton still remaining white, or having but a very slight tint upon it. The cotton is then prepared to receive the colour, by working the goods in a cold solution of galls or sumac, the former being preferable, after which they are worked in a cold dilute solution of neutral chloride of tin. When sumac is used those processes give a buff tint to the cotton, which is objectionable, and can be removed by working the goods in a cold solution of oxalic acid, which will not deteriorate the mordant. The goods are well washed in cold water after the chloride of tin, and also after the oxalic acid. When that article is used the cotton has now received a mordant which enables it to take up the colour, either hot or cold, but experience has proved that the colour is brighter when the cotton is dyed cold; and, consequently, it must be dyed last. The only thing requisite is to add colouring sufficient to a proper quantity of cold water, and work the goods in it till the colour is even upon the cloth, after which they are washed in cold water, then dyed, and finished.

The objections to the colour supplied in powder in the above processes are, that in dyeing worsted a duller colour is produced, and there is an additional objection, which presents itself in the cold process, which bath is not emptied for weeks together, and when the colour is dissolved from the powder by boiling water, and the solution added to the cold bath, it immediately begins to precipitate, from the fact of there being no solvent present to hold the colour in solution. (As I stated before, hot water will hold the colour in solution, but when the aqueous solution becomes cold, it will precipitate.) The sides of the vessel receive a coating of the precipitate, and then the goods come in contact with it, when, in addition to being a bad or inferior colour, they are all stained with the precipitate. There are other objections, but the above will show that dyers are more willing to give things a fair trial, than some manufacturers are to admit their errors.—I am, &c.

JAMES SHARP.

Leeds.

MISCELLANEOUS.

Emery.—The trade in emery is not, as formerly, monopolised by the Greek Government, which now levies a tax of 5 drachms per hundred weight when exported. Other hard minerals are sometimes fraudulently substituted for it, to detect which, and to determine the value of the emery, the following method is employed in Smyrna:—A plate of glass of known weight is rubbed with a certain quantity of the emery until it has no further effect; the lighter the glass has become, the better is the quality of the emery. The emery diggings of the Government are on the island of Naxos. A ferruginous clay silicate has lately been discovered upon the island of Skyno, which is not inferior in hardness to emery.—*Wittst. V. Schr.* ix. 535.

Commercial Products of the Asphodel.—Every one is familiar with the pretty, lovely-looking, white-flowered asphodel of our gardens. In the South of Europe, and apparently on both sides of the basin of the

Mediterranean, the plant (*Asphodelus ramosus*) is extremely abundant; though it has never, so far as I know, been turned to any account, except that in times of scarcity its acrid fasciculated roots, after much coiling, have been eaten by the poor. In the Paris Exhibition of 1855 there were shown bottles of alcohol extracted from the asphodel; specimens of the residuum of the roots after being twice distilled; paper stuff from the stalks and leaves of asphodel—card-paper, cards, paper and writing-papers, of various qualities, manufactured from the same, and mixed in various proportions with rags and common paper stuff. M. de la Bertoche in a pamphlet, asserts that asphodel roots contain upwards of 27 per cent. of alcoholic principle, or more than double the quantity which resides in the root of beet. The stalks and leaves contain a remarkably tenacious fibre, fine, strong, and flexible. The distillation of asphodel root has been already pursued, and with considerable success, in Algeria; but the immense abundance of the plant in Tuscany, where it has hitherto been considered only a pernicious and most ineradicable weed, points to the advantage of endeavouring to turn it to account. The fasciculated roots, after cleansing and crushing, are mixed with water, and the fluid is exposed to heat, so as to facilitate fermentation. The alcohol which it yields is pure and colourless, perfectly transparent, and has the colour of alcohol itself. It contains neither acid salt, nor oily matter; it burns without leaving any residue, and the flame is remarkably bright. But at the present time, when material for paper seems likely to fail, a most important succedaneum is afforded by the remains of asphodel. It is undeniable that the residuum of the roots after distillation, together with the other parts of the plant, are eminently adapted to this object. Three processes are necessary; the separation of the useful portions,—the bleaching,—and the reducing the substances into a homogeneous and tenacious pulp. The first is better effected by crushing than by grinding, as the latter mode is apt to destroy the fibre. The second operation involves most difficulty, as the root is covered with a skin which contains a tanning principle; and it is necessary, unless the expensive mode of hand-picking the root be adopted, to expose the substance to air and light, aided by immersion in diluted chlorine, which brings the substance to a very pale brown tint, which is not objectionable for many sorts of paper. For the third process, that of reducing the whole mass to a smooth and tenacious paste, the paper manufacturers must supply the details.—*Sir W. J. Hooker, K.H., F.R.S., in the Technologist.*

ANSWERS TO CORRESPONDENTS.

Permanent Marking Ink.—Indian ink, or the finest lamp-black, with a solution of shellac in borax gives an ink which is not affected by chlorine or cyanide of potassium, or by acids. No nitrate of silver is necessary.

Varnish for Iron.—The best varnish for iron chains is made of pure linseed oil well boiled and rendered quick drying by adding some litharge—about four ounces to the gallon. Colour it black by adding some lamp-black and a little asphalt. When resin is added to oil it renders it more liable to scale off. The chains should be thoroughly dried in a hot room before they are used.

Pigmy.—The subject is one which has occupied the attention of scientific men for some years. It has, however, never yet been really accomplished.

F. R. G.—In September next.

A Victim.—Your case is hard, but you would gain nothing by taking proceedings. What is the use of winning an action against a pauper? He could not pay any expenses.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Estimation of Commercial Saltpetres, by M. J. PERSOZ.

THE best method for estimating the water is to melt carefully from 50 to 200 grammes of nitre in a platinum capsule, taking care that the temperature is not raised much above the fusing point. Weigh the crucible immediately after cooling. If the saltpetre contains nitrate of lime or magnesia add about 1 gramme of well-dried neutral chromate of potash, which prevents loss of nitric acid from these nitrates, so easily decomposed by heat.

To estimate insoluble matters, treat the melted mass with water so as to form a determinate volume of solution N. Filter this carefully; collect, wash, and weigh the insoluble precipitate.

Gay-Lussac's method employed for the estimation of chlorides is to use two standard solutions, one containing 27 grammes and the other 2.7 grammes of pure silver to the litre. Each cubic centimetre of the stronger solution corresponds to 0.01466 grammes of chloride of sodium or 0.01864 grammes of chloride of potassium.

To estimate sulphates, a standard solution of chloride of barium is used, containing 259.8 grammes of salt, each cubic centimetre representing 0.179 grammes of sulphate of soda, or 0.208 grammes of sulphate of potassa. The operation is conducted in the following manner:—Measure 200 cubic centimetres of the solution N of nitre; after adding a few drops of acid, introduce it into a platinum capsule and boil it freely; then carefully pour in a slight excess of standard solution. At this point of the process fill a graduated burette with the solution N, and add it, little by little, until the excess of barytic standard solution is exactly precipitated. This last operation is somewhat tedious and difficult, because the solutions do not readily become clear, and it is often necessary to filter small trial quantities. The relation between the total volume of N employed and the volume of barytic standard solution gives the proportion of sulphate in a given weight of nitre.

Nitric acid is estimated in a very elegant manner, by using dry bichromate of potash, which expels nitric acid from the alkaline nitrates without decomposing the chlorides. The operation is thus conducted:—On a lump of saltpetre, melted and cooled, weighing from 2 to 5 grammes, and placed in a small but sufficiently large platinum crucible, place about twice its weight of previously melted and pulverised bichromate of potash. Weigh, and then carefully heat the whole. At first the reaction is somewhat energetic, and it frequently happens that considerable quantities of the mixture are carried off and are condensed on the inner surface of the cover, which should be shaped like a deep capsule, so that the

fusible matter projected against it may fall in the crucible. In proportion as the nitrous vapours diminish raise the temperature to a dull red heat, taking care to equalise the temperature of the cover by directing a gas jet on it. When the operation is finished leave the crucible uncovered for a few instants, that the air in it may be renewed; allow it to cool, and weigh it. The loss of weight indicates the quantity of nitric acid displaced, from which may be calculated the corresponding proportion of nitrate of potash or soda.

If the nitrate analysed contains at the same time potash and soda an excess will be found by converting the estimated nitric acid into nitrate of potash; and, on the contrary, a deficiency, by converting the acid into nitrate of soda. This excess or deficiency allows of the calculation of the relative proportion of the two alkaline nitrates in the salt analysed.—*Annales du Conservatoire des Arts et Metiers.*

On the Preparation of an Ethereal Solution of Binoxide of Hydrogen.

THIS has been recommended by Dr. H. Storer as a test for chromic acid. Professor R. Böttger proposes the following method for preparing a solution which will keep unaltered for a long time. A piece of sodium, of the size of a hazel-nut, and freed from petroleum, is heated in a rather flat, somewhat inclined porcelain capsule, over a Bunsen gas burner, to fusion, so that it ignites when stirred in contact with the air by means of an iron rod. As soon as the burning and glowing ceases, it is transferred to a well-stoppered vial. Of this impure binoxide of sodium, small particles are carried into about an ounce of very dilute sulphuric acid (1 to 24 water) contained in a narrow cylinder which is kept cool. After the third or fourth introduction, ether is added, the liquids agitated, and after separation the ether removed; this may be continued until the ethereal solution ceases to produce an intensely blue colour with a diluted solution of chromic acid. With little material, a considerable quantity of this new reagent is produced in a short time.—*Wittst. V. Schr.* ix. 546.

On the Employment of Hypochloric Acid as an Oxidiser and Solvent, by M. BRUNNER.

ORES, attacked with considerable difficulty, are easily oxidised by nascent hypochloric acid—for instance, chrome iron, sulphide of molybdenum, uranium ore, &c. M. Brunner recommends mixing the ores, reduced to an impalpable powder, with eight times their weight of chlorate of potash, placing the mixture in a flat-bottomed capsule, and pouring into it sulphuric acid diluted with one-half to once and even twice its volume of quite cold water.

The more easily attacked the ore, the more should the

sulphuric acid be diluted. Acid with half its volume of water may be used for chrome iron. It requires stirring from time to time without the application of heat, and not till the expiration of twenty-four hours can the operation be terminated by the application of a gentle heat. 15 cubic centimetres of sulphuric acid are sufficient for 1 gramme of chrome ore, and it should be added in two portions. Crystals of chromic acid gradually appear in the mixture.

By avoiding raising the temperature, and the use of an acid too concentrated, there need be no fear of explosions, in which there is really no danger, but which may occasion loss of material.—*Repertoire de Chimie.*

TECHNICAL CHEMISTRY.

On Aluminium Bronze, by BARNARD S. PROCTOR.

THE chemical relations of aluminium and the mechanical properties of aluminium bronze have had frequent notice, and may be said to have been fairly introduced to the notice of those who are likely to make use of either material in the arts or manufactures; but the question of how far the chemical affinities of the copper are modified by its union with aluminium appears to have had less attention than it deserves.

The following simple experiments comparing the relative powers of aluminium bronze and ordinary brass to withstand the action of various agents were designed to point out how far the new material could offer advantages over brass for the construction of apparatus, philosophical instruments, or domestic utensils:—

BRONZE FILINGS.

BRASS FILINGS.

No. 1. *With Nitric Acid, 1.42.*

Acted freely, not violently. Acted violently.

No. 2. *Dilute Nitric Acid, P. L.*

No evident action while cold, acted freely while boiling, but ceased again on cooling. A feeble action while cold, a free action while hot boiling, but reduced again on cooling.

No. 3. *Dilute Hydrochloric Acid, P. L.*

No evident action, either cold or hot. The acid being boiled for a minute upon the filings and decanted gave no indication with ammonia, but with sulphuret of ammonia, on standing a few hours, there was evident dark precipitate. In every particular the same as the bronze.

No. 4. *Dilute Nitric and Hydrochloric Acids Mixed.*

Slowly but completely dissolved. Dissolved a little more quickly.

No. 5. *Strong Hydrochloric Acid.*

No evident action while cold, and only feeble on boiling, the colour produced with ammonia being just visible, and with the sulphuret clearly evident. Similar to the bronze, but the action a little more evident.

No. 6. *Dilute Sulphuric Acid.*

With a few seconds' boiling, did not give indication with ammonia, but coloured strongly with the sulphuret. Acted the same as the bronze, but a little more strongly.

No. 7. *Acetic Acid, P. L. Strength.*

A few filings in the bottom of the tube containing the acid were considerably acted upon in the course of fourteen hours, the liquor being dark green, and many small green crystals upon the sides of the tube, apparently from the action of the vapour upon the filings which had adhered to the glass. Not evidently more acted upon than the bronze.

No. 8. *Solution of Ammonia, '960 specific gravity, in the bottom of a tube.*

The action of air, moisture, and ammonia for twenty-four hours dissolved the few filings which had been placed in the tube, producing a blue liquor and white precipitate. Similar to the bronze, but without the precipitate.

A piece of bronze cut from the ingot, hammered flat, filed to a smooth surface, and finished with fine emery-paper, and a piece of brass tube treated in the same manner were subjected to the following experiments, being cleaned with emery-paper between each:—

No. 9. The metals were wrapped in paper and placed in a jar of sesquicarbonate of ammonia. After a few hours the brass was black, and the paper stained blue; the bronze did not seem to have been acted upon. After twenty-four hours a slight action was perceptible upon the bronze, there being a few blue specks upon the metal and blue spots upon the wrapper, but the general surface of the metal still clean. After several days, the spots had increased, but the general surface was scarcely acted upon.

No. 10. Wrapped in paper and placed in a jar of sulphuret of potassium, were not tarnished perceptibly in twenty-four hours. On being wetted and returned to the jar, they were both tarnished, but the bronze less than the brass.

No. 11. Sprinkled with carbonate of potash, which was allowed to deliquesce upon their surface, in two hours the brass was evidently tarnished; in twelve hours considerably tarnished. The bronze unaltered after twenty-four hours.

No. 12. Sprinkled with acetate of potash, in two hours brass was evidently acted upon; in twelve hours considerably tarnished, the spots where the salt had deliquesced being almost black. In twenty-four hours the bronze had suffered nothing, its surface being clean and simply moist with the deliquesced salt.

No. 13. Half covered with a weak solution of tartaric acid, both became gradually tarnished, and in forty-eight hours were covered with thin, adhering crusts, white on the bronze, black on the brass. The crusts did not wash off nor rub off, except with hard friction. The water with which the acid had been washed off gave distinct but not copious blue with ammonia.

No. 14. As No. 13, but with citric acid. Both were tarnished, but much less so than in the last. The coating upon the bronze was thin, green, and tarnish-like. The washings gave with ammonia much stronger indications than No. 13, showing that the discoloration of the surface is not a fair indication of the quantity of metal dissolved.

No. 15. Sprinkled with cream of tartar and water

and allowed to dry. The tartarate upon both had become greenish, and the surface tarnished, but less upon the bronze than the brass.

No. 16. Treated as No. 15, but with binoxalate of potassa. The action similar but stronger. The bronze again was least acted upon.

No. 17. Exposed to a moist atmosphere containing ammonia. Eight hours: the brass was much blackened, the bronze slightly tarnished; twenty-four hours: the corrosion of the brass had gone on rapidly, its surface being black, rough, and covered with small drops of blue liquid; the bronze was dull, but not much discoloured, and there were few small specks of blue liquid upon its surface.

No. 18. Exposed to the fumes of a solution of hydro-sulphuret of ammonia, a drop of the solution also being placed upon the metals. In five minutes the brass was considerably acted upon by the solution, but scarcely at all by the vapour. The bronze was almost instantly tarnished by the vapour, but very little acted upon by the solution. In half-an-hour the brass was tarnished yellow over its general surface, and the edges were black. The action on the bronze did not seem to have increased.

No. 19. Exposed to moist air containing sulphuretted hydrogen. The bronze was almost instantly discoloured, but the brass scarcely visibly so. After remaining a few days under this action the metals appeared acted on to much the same extent, but the brass had an orange coloured tarnish, spotted with black; the bronze a greenish-grey tarnish, likewise spotted with black. (Compare Experiment No. 10.)

No. 20. Exposed to a moist air containing chlorine. Eight hours produced a very slight tarnish upon both. The quantity of chlorine being considerably increased so as to smell pungent, the action became considerable; in the course of a few hours a green crust was formed upon both, which, when scraped off left the brass with a dirty surface, but the bronze almost clean.

No. 21. Exposed to the fumes of nitric acid, specific gravity 1.42, eight hours. Both metals were acted upon and moist, the brass being black, the bronze not much discoloured, but having a loose precipitate which easily wiped off its surface.

No. 22. Exposed to the fumes of hydrochloric acid, specific gravity 1.16, one hour. The brass was growing black at the edges, and its whole surface somewhat dull; the bronze almost equally dull, but not black at the edges. Thirty-six hours: brass covered with a strongly adhering, smooth black crust, upon which was standing a considerable quantity of green solution containing green crystals; the bronze was covered with a pale slate-grey precipitate, moist, and easily rubbed off, leaving the surface perceptibly roughened. Examined with a one-inch lens, it had the appearance of crystalline structure. The brass, after cleaning with ammonia and sulphuric acid, exhibited a surface somewhat less roughened and not crystalline.

No. 23. Exposed to the action of moist air containing sulphurous acid. The change was slow; eight hours rendered the surfaces dull, that of the bronze somewhat copper-coloured. The quantity of sulphurous acid being increased so as to smell pungent, the brass soon acquired a thin but quite perceptible film upon its centre. In fourteen hours the brass was dark green-brown, and coated with crystals; the bronze of a copper-brown, with crystals and solution by deliquescence. Washing with water removed most part of the film from both. Under a one-inch lens the brass was distinctly pitted;

the bronze was pitted much more minutely, being scarcely distinguishable with one inch focus.

No. 24. Exposed to the vapour of iodine at 70° F. Both were acted upon about equally quickly. After eight hours the bronze had a grey-white film, which easily rubbed off, leaving the surface little altered; the brass had a grey-black film, part of which rubbed off readily, and left the surface bright but black.

No. 25. Exposed to the action of salt water. Twelve hours produced a little discoloration of the brass, but no visible change upon the bronze. Twenty-four hours: the salt having crystallised upon the metals, the bronze was slightly dull after washing with water; the brass dull grey, tarnished, the metallic lustre being slightly visible through the coating.

No. 26. Exposed to vinegar, which was allowed slowly to evaporate upon them. The brass was much discoloured, and had green crystals on its surface; the bronze very little discoloured, but slightly more crystals upon it. Under the microscope the brass seemed most uniformly acted upon, there being a general roughness over its surface. The bronze in places was corrugated, as if from an indistinct crystalline texture.

No. 27. Exposed to ordinary coal-gas within the gas-fittings, where a slow current passed over them for eight or ten hours per day, the sample remaining in a stationary charge of gas during the remainder of the twenty-four hours. One week produced scarcely any change; two weeks, the general surface of the metals was tarnished, and the brass strongly discoloured at the edges.

No. 28. The metals, after being burnished, were exposed to the air in the shop (Pharmaceutical). Five days: bronze had an orange-yellow tarnish; brass a greenish-grey tarnish about equal in depth.

No. 29. Burnished and exposed to the weather on the roof of the house. Five days: rain, wind, and sunshine repeatedly alternated. Bronze little tarnished, and little spotted; the brass was considerably more tarnished, spotted, had a black discoloration round the edge, and was more difficult to clean.

No. 30. A repetition of No. 28, the surfaces instead of being burnished were cleaned with fine powdered pumice and oxalic acid. Results the same as No. 28.

No. 31. A repetition of No. 29, with cleaned instead of burnished surfaces, gave similar results—if anything, still more strongly in favour of the bronze.

From the above experiments, it appears that the bronze has a little advantage over ordinary brass in its power of withstanding corrosion, and that its surface, when tarnished, is more readily cleansed. This should give it a general preference where cost of material is not an important consideration, especially if strength, lightness, or durability is at the same time desirable. It would be out of my province to say anything with regard to its fitness for delicate machinery, such as clocks and watches, except that its chemical examination has revealed nothing which can detract from the preference which its mechanical superiority should give it.

Being so much less acted upon by ammoniacal salts and coal gas (see Experiments 9, 17, 18), it appears to offer advantages for the construction of gas-metres, stop-cocks, and moveable joints in gas-fittings.

Its withstanding the action of some deliquescent salts (see Experiments 11, 12), suggests its suitability for chemists' scales and weights, scoops, &c. Its resistance to the action of the weather, and the ease with which the tarnish is removed, renders it specially applicable for door-plates, bell-handles, &c. Its mechanical strength

and chemical inactivity together recommend it for hinges, &c., which are to be exposed to the weather.

In Experiments 18, 22, 27, 29, the tendency of brass to corrosion at its edges, and at any roughness upon its surface, will be observed, and that the bronze is free from this defect.

In several cases (e.g. Nos. 18 and 19), the bronze seemed to be most quickly covered with a slight tarnish, which did not increase perceptibly, probably the tarnish acting as a protection to the metal; but the brass, though less rapidly discoloured, continued to be corroded, apparently with increased speed as the action was continued.

In Experiments No. 20, 21, 22, 29, we find the bronze to be much more easily cleaned, a circumstance of considerable importance in its application to many purposes.

For culinary vessels its superiority to the materials now in use appears questionable.

Drawing instruments, pneumatic apparatus, stage fittings for microscopes, telescope tubes, and various other philosophical instruments are among the purposes for which the use of the bronze appears advantageous.

Undoubtedly, the greatest obstacle to its extensive application is its high price, resulting partly, it is said, from the great difficulty of procuring copper in a state of sufficient purity for the production of a good bronze, the presence of a small portion of iron, &c., being very prejudicial. But surely, the talent which has removed aluminium from its position among the rare minerals of the cabinet to an article of commerce, which has already reduced its price from 60*l.* to 6*s.* per lb., will not be long in devising the means of producing both aluminium and pure copper at a still more moderate price.

11, Grey Street, Newcastle-upon-Tyne.

P.S.—With a home-made pen of aluminium-bronze I add a postscript to my article, to suggest that this material is well worthy the attention of steel-pen makers. From two days' work with this badly-constructed pen, I anticipate that the material will, when well worked, be found to possess both chemical and mechanical properties to recommend it for this purpose.

*On the Best Form for Chimneys, by L. C. LEVOIR,
Phil. Nat. Doct., Leyden University.*

It is a long discussed question, whether chimneys should be made conical with the largest base beneath, cylindrical, or conical with the largest opening at the outlet in the air. Some time ago I tried an experiment which apparently showed that the last form was the best one.

When two adjacent gas-flames are caused to burn from the same tube, the outlets being equal, and about a quarter of an inch wide, and the pressure very low, the flames have the same length when placed in the same horizontal level. But as soon as one is placed higher than the other that one becomes taller by the diminution of pressure higher in the atmosphere.

By putting a conical tube of about three feet in length on one of the flames, when they are burning equal, the greatest suction results when the conical tube is placed with the largest end upwards. The greater suction is not resulting from the higher temperature which the smaller end of the tube assumes, owing to its being placed so much nearer to the flame, for a stream

of cold water flowing round the tube does not occasion a greater length of the flame on which the conical tube is not adapted.

This experiment is a confirmation of a fact which several engineers have long since observed. The reason why so many chimneys are still built cylindrical, or conical, with the widest section beneath, seems to me to be that the influence of the winds—especially those occurring in the daytime, which seem to have a less horizontal direction than those at night—interferes more with the flowing out of the products of combustion as the outlet of the chimneys become wider. Suitable covering head-pieces, to turn with the wind, would highly improve the suction in conical chimneys, and also prevent the smoke from blowing down in so inconvenient a manner.

PHARMACY, TOXICOLOGY, &c.

On the Use of Phenic Acid for Disinfecting Purposes, and its Mode of Action, by M. J. LEMAIRE.

SINCE MM. Corne and Demeaux's paper on "Coal-tar" was presented to the Academy, M. Dumas has stated that the disinfecting properties of this body are due to phenic acid. M. Lemaire's experiments prove this opinion correct. He has witnessed the efficacy of phenic acid dissolved or made into emulsion in the preservation of animal matters. Phenic acid made into an emulsion and injected into the bodies of animals will preserve them unaltered in contact with the air; a human adult body can be preserved with less than 50 centimes.

The author has already indicated an important application of phenic acid to the destruction of parasites. An aqueous solution of 1 per cent. of this acid, and 40 per cent. of acetic acid removes tinea in 30 or 40 days, and cures itch speedily. Acetic acid is added to the preparation, to enable the medicament to penetrate the epidermis, so as to reach the bulbs of the hair. I am of opinion that the same solution would serve to destroy domestic insects; the powders used for this purpose are effective, but the solution would penetrate better into the crevices of furniture.

*On Medicinal Aconitine and its Substitutes,
by WILLIAM PROCTER, jun.*

THE high price and variable quality of aconitine has rendered its use as a medicinal agent so expensive and uncertain, that many physicians never employ it, depending upon the stronger tinctures of the root, in cases requiring the external use of aconite. In the manufacture of organic chemical products very much is added to their cost by the complications and loss rendered necessary or unavoidable in their purification from colouring matter, or strongly adherent resinous or other inert substances in minute quantity, which, while their presence impairs the market value of the chemicals, often do not greatly reduce their medicinal power. In asking the attention of pharmacutists to the following modification of Headland's process for aconitine, it is with the view of furnishing them with a practicable means of supplying their own wants in regard to this potent alkaloid.

It is proper to premise that aconite root contains a

¹ It will give us much pleasure to receive further communications from this Correspondent.—Ed. C. N.

green fixed oil, solid below 70° Fahr., which it is important to remove entirely from the solution, before attempting to extract the alkaloid by the agency of ether, a precaution only partially carried out in the published process of Dr. Headland. When a tincture of aconite root in alcohol of sp. gr. .835, whether prepared in the cold by percolation or by digestion at the temperature of boiling alcohol, as recommended by Headland, is evaporated to one-half the weight of the root treated, a quantity of the green fatty oil above noticed separates and floats upon the surface of the liquid. Most of this may be strained out, if the temperature is below 70° Fahr., but a portion, together with some resin, remains intimately combined in the clear liquid, and it is this which is not removed previously to adding the ammonia, in the process of Headland. Further, aconitic acid is soluble in ether, and aconite of ammonia may be slightly so, in which case it also would tend to contaminate the aconitine in that process.

Take of aconite root, in fine powder, five pounds; alcohol .835, ether, and strong solution of ammonia, of each a sufficient quantity. Moisten the aconite root with two pints of alcohol, and let it stand twenty-four hours in a covered vessel, then, having packed it closely in a cylindrical percolator, pour on alcohol until three gallons have slowly passed, or until the root is so far exhausted that the passing liquid has little, if any, taste of aconite. To the tincture thus formed, add an ounce of lime, previously hydrated and in powder, and agitate them together, separate the precipitate which forms, by straining through a close cloth, and saturate the liquid with diluted sulphuric acid till slightly acid. Filter the liquid through a close filter, and distil off the alcohol, until the remaining liquid measures about a pint and a-half. Remove any fixed oil which may separate on standing, and having continued the evaporation to a syrupy consistence, agitate it well with four fluid ounces of ether in a suitable bottle, and decant the ether when it has separated. Then add the solution of ammonia in excess, agitate thoroughly, wash the mixture with repeated portions of ether, by agitation and decantation, and having mixed these last ethereal liquids, allow the ether to evaporate spontaneously from a capsule, until the aconitine remains as a dry, amorphous, shining residue, which should be removed from the capsule, powdered, and preserved for use in a stoppered vial.

As thus obtained, aconitine is a powder of greenish or brownish-white colour, uncrystallised, very soluble in alcohol, ether, and chloroform, saturates acids, and has a strong alkaline reaction. It irritates the nose powerfully when a minute particle is inhaled, but does not excite sneezing.

Modes of Using Aconitine.—When aconitine is to be employed in the form of an ointment, its activity may be much increased by adding to it a sufficiency of acetic acid to salify it, which renders it more readily absorbable in contact with the skin. The powder should first be triturated with a few drops of alcohol, and the acid added to this, in the proportion of a drop of acetic acid to each grain of the alkaloid.

Glycerole.—When aconitine is mixed with a slight excess of acetic acid, it readily dissolves in glycerin, and in this state may be applied by friction to the surface requiring its anæsthetic action. The proportion of the alkaloid to each preparation must be regulated by the prescriber; two or three grains to the drachm of prepared lard is a maximum strength for the ointment, and from this down to one grain.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Weekly Evening Meeting, Friday, June 7, 1861.

The Duke of Northumberland, K.G., F.R.S., President, in the Chair.

On the Physical Basis of Solar Chemistry, by JOHN TYNDALL, Esq., F.R.S., Professor of Natural Philosophy, Royal Institution.

OMITTING all preface, the speaker drew attention to an experimental arrangement intended to prove that gaseous bodies radiate heat in different degrees. Behind a double screen of polished tin was placed an ordinary ring gas-burner; on this was placed a hot copper ball, from which a column of heated air ascended; behind the screen, but so placed that no ray from the ball could reach the instrument, was an excellent thermo-electric pile, connected by wires with a very delicate galvanometer. The thermo-electric pile was known to be an instrument whereby heat was applied to the generation of electric currents, the strength of the current being an accurate measure of the quantity of the heat. As long as both faces of the pile were at the same temperature no current was produced; but the slightest difference in the temperature of the two faces at once declared itself by the production of a current, which, when carried through the galvanometer, indicated by the deflection of the needle, both its strength and its direction.

The two faces of the pile were in the first instance brought to the same temperature; the equilibrium being shown by the needle of the galvanometer standing at zero. The rays emitted by the current of hot air already referred to were permitted to fall upon one of the faces of the pile; and an extremely slight movement of the needle showed that the radiation from the hot air, though sensible, was extremely feeble. Connected with the ring-burner was a holder containing oxygen gas; and by turning a cock, a stream of this gas was permitted to issue from the burner, strike the copper ball, and ascend in a heated column in front of the pile. The result was, that oxygen showed itself, as a radiator of heat, to be quite as feeble as atmospheric air.

A second holder, containing olefant gas, was also connected by its own system of tubes with the ring-burner. Oxygen had already flowed over the ball and cooled it in some degree. Hence, as a radiator, in comparison with oxygen, the olefant gas laboured under a disadvantage. It was purposely arranged that this should be the case; so that if, notwithstanding its being less hot, the olefant gas showed itself a better radiator, its claim to superiority in this respect would be decisively proved. On permitting the gas to issue upwards, it cast an amount of heat against the adjacent face of the pile sufficient to impel the needle of the galvanometer almost to its stops at 90°. This experiment proved the vast difference between two equally transparent gases with regard to their power of emitting radiant heat.

The converse experiment was now performed. The thermo-electric pile was removed and placed between two cubes filled with water kept in a state of constant ebullition; and it was so arranged that the quantities of heat falling from the cubes on the opposite faces of the pile were exactly equal, thus neutralising each other. The needle of the galvanometer being at zero, a sheet of oxygen gas was caused to issue from a slit between one of the cubes and the adjacent face of the pile. If this sheet of gas possessed any sensible power of intercepting the thermal rays from the cube, one face of the pile being deprived of the heat thus intercepted, a difference of temperature between its two faces would instantly set in, and

the result would be declared by the galvanometer. The quantity absorbed by the oxygen under those circumstances was too feeble to affect the galvanometer; the gas, in fact, proved sensibly transparent to the rays of heat. It had but a feeble power of radiation; it had an equally feeble power of absorption.

The pile remaining in its position, a sheet of olefiant gas was caused to issue from the same slit as that through which the oxygen had passed. No one present could see the gas. It was quite invisible; the light went through it as freely as through oxygen or air; but its effect upon the thermal rays emanating from the cube was what might be expected from a sheet of metal. A quantity so large was cut off that the needle of the galvanometer, promptly quitting the zero line, moved with energy to its stops: thus, the olefiant gas, so light and clear and pervious to luminous rays, was a most potent destroyer of the rays emanating from an obscure source. The reciprocity of action established in the case of oxygen comes out here; the good radiator is found by this experiment to be the good absorber.

This result, which was exhibited before a public audience this evening for the first time, was typical of what had been obtained with gases generally. Going through the entire list of gases and vapours in this way, we should find radiation and absorption to be as rigidly associated as positive and negative in electricity, or as north and south polarity in magnetism. The gas which, when heated is most competent to generate a calorific ray, is precisely that which is most competent to stop such a ray. If the radiation be high, the absorption is high; if the radiation be moderate, the absorption is moderate; if the radiation be low, the absorption is low; so that if we make the number which expresses the absorptive power the numerator of a fraction, and that which expresses its radiative power the denominator, the result would be, that, on account of the numerator and denominator varying in the same proportion, the value of that fraction would always remain the same, whatever might be the gas or vapour experimented with.

But why should this reciprocity exist? What is the meaning of absorption? What is the meaning of radiation? When you cast a stone into still water, rings of waves surround the place where it falls; motion is radiated on all sides from the centre of disturbance. When the hammer strikes a bell, the latter vibrates; and sound, which is nothing more than an undulatory motion of the air, is radiated in all directions. Modern philosophy reduces light and heat to the same mechanical category. A luminous body is one with its particles in a state of vibration; a hot body is one with its particles also vibrating, but at a rate which is incompetent to excite the sense of vision; and, as a sounding body has the air around it, through which it propagates its vibrations, so also the luminous or heated body has a medium, called ether, which accepts its motions and carries them forward with inconceivable velocity. Radiation, then, as regards both light and heat, is the transference of motion from the vibrating body to the ether in which it swings; and, as in the case of sound, the motion imparted to the air is soon transferred to the surrounding objects, against which the aerial undulations strike, the sound being, in technical language, absorbed; so also with regard to light and heat, absorption consists in the transference of motion from the agitated ether to the particles of the absorbing body.

The simple atoms are found to be bad radiators; the compound atoms good ones; and the higher the degree of complexity in the atomic grouping, the more potent, as a general rule, is the radiation and absorption. Let us get definite ideas here, however gross, and purify them afterwards by the process of abstraction. Imagine our simple atoms swinging like single spheres in the ether; they cannot create the swell which a group of them united to form a system can produce. An oar runs freely edgeways

through the water, and imparts far less of its motion to the water than when its broad, flat side is brought to bear upon it. In our present language, the oar, broad side vertical, is a good radiator; broad side horizontal, it is a bad radiator. Conversely, the waves of water, impinging upon the flat face of the oar-blade, will impart a greater amount of motion to it than when impinging upon the edge. In the position in which the oar radiates well it also absorbs well. Simple atoms glide through the ether without much resistance; compound ones encounter this, and yield up more speedily their motion to the ether. Mix oxygen and nitrogen mechanically, they absorb and radiate a certain amount. Cause these gases to combine chemically and form nitrous oxide, both the absorption and radiation are thereby augmented 250 times!

In this way we look with the telescope of the intellect into atomic systems, and obtain a conception of processes which the eye of sense can never reach. But gases and vapours possess a power of choice as to the rays which they absorb. They single out certain groups of rays for destruction, and allow other groups to pass unharmed. This is best illustrated by a famous experiment of Sir David Brewster's, modified to suit the requirements of the present discourse. Into a glass cylinder, with its ends stopped by discs of plate glass, a small quantity of nitrous acid gas was introduced; the presence of the gas being indicated by its rich brown colour. The beam from an electric lamp being sent through two prisms of bisulphide of carbon, a spectrum seven feet long and eighteen inches wide was cast upon a screen. Introducing the cylinder containing the nitrous acid into the path of the beam as it issued from the lamp, the splendid and continuous spectrum became instantly furrowed by numerous dark bands, the ray answering to which were struck down by the nitric gas, while it permitted the light which fell upon the intervening spaces to pass with comparative impunity.

Here, also, the principle of reciprocity, as regards radiation and absorption, holds good; and could we, without otherwise altering its physical character, render that nitrous gas luminous, we should find that the very rays which it absorbs are precisely those which it would emit. When atmospheric air and other gases are brought to a state of intense incandescence by the passage of an electric spark, the spectra which we obtain from them consist of a series of bright bands. But such spectra are produced with the greatest brilliancy, when, instead of ordinary gases, we make use of metals heated so highly as to volatilise them. This is easily done by the voltaic current. A capsule of carbon was filled with mercury, which formed the positive electrode of the electric lamp; a carbon point was brought down upon this; and on separating one from the other, a brilliant arc containing the mercury, in a volatilised condition passed between them. The spectrum of this arc was not continuous, like that from the solid carbon points, but consisted of a series of vivid bands, each corresponding in colour to that particular portion of the spectrum to which its rays belonged. Copper gave its system of bands; zinc gave its system; and brass, which is an alloy of copper and zinc, gave a splendid spectrum made up of the bands belonging to both metals.

Not only, however, when metals are united, like zinc and copper, to form an alloy is it possible to obtain the bands which belonged to them. No matter how we may disguise the metal—allowing it to unite with oxygen to form an oxide, and this again with acid to form a salt; if the heat applied be sufficiently intense, the bands belonging to the metal reveal themselves with perfect definition. Holes were drilled in a cylinder of retort carbon, and these being filled with pure culinary salt, the carbon was made the positive electrode of the lamp: the resultant spectrum showed the brilliant yellow lines of the metal sodium. Similar experiments were made with the chlorides of

strontium, calcium, lithium,¹ and other metals; each salt gave the bands due to the metal. Different salts were then mixed together, and rammed into the holes in the carbon. A spectrum was obtained which contained the bands of them all.

The position of these bright bands never varies, and each metal has its own system. Hence the competent observer can infer from the bands of the spectrum the metals which produce it. It is a language addressed to the eye instead of the ear; and the certainty would not be augmented if each metal possessed the power of audibly calling out, "I am here!" Nor is this language affected by distance. If we find that the sun or the stars give us the bands of our terrestrial metals it is a declaration on the part of these orbs that such metals enter into their composition. Does the sun give us any such intimation? Does the solar spectrum exhibit bright lines which we might compare with those produced by our terrestrial metals, and prove either their identity or difference? No. The solar spectrum, when closely examined, gives us a multitude of fine dark lines instead of bright ones. They were first noticed by Dr. Wollaston, were investigated with profound skill by Fraunhofer, and named from him Fraunhofer's lines. They have been long a standing puzzle to philosophers. The bright lines which the metals give us have been also known to us for years; but the connection between both classes of phenomena was wholly unknown, until Kirchhoff, with admirable acuteness, revealed the secret, and placed it at the same time in our power to chemically analyse the sun.

We have now some hard work before us. Hitherto we have been delighted by objects which addressed themselves rather to our æsthetic taste than to our scientific faculty. We have ridden pleasantly to the base of the final cone of Etna, and must now dismount and march wearily through ashes and lava if we would enjoy the prospect from the summit. Our problem is to connect the dark lines of Fraunhofer with the bright ones of the metals. The white beam of the lamp is refracted in passing through our two prisms, but its different components are refracted in different degrees, and thus its colours are drawn apart. Now the colour depends solely upon the rate of oscillation of the particles of the luminous body; red light being produced by one rate, blue light by a much quicker rate, and the colours between red and blue by the intermediate rates. The solid incandescent coal-points give us a continuous spectrum; or in other words, they emit rays of all possible periods between the two extremes of the spectrum. They have particles oscillating so as to produce red, others to produce orange, others to produce yellow, green, blue, indigo, and violet respectively. Colour, as many of you know, is to light what *pitch* is to sound. When a violin player presses his finger on a string he makes it shorter and tighter, and thus, causing it to vibrate more speedily, augments the pitch. Imagine such a player to move his finger slowly along the string, shortening it gradually as he draws his bow, the note would rise in pitch by a regular gradation; there would be no gap intervening between note and note. Here we have the analogue to the continuous spectrum, whose colours insensibly blend together without gap or interruption, from the red of the lowest pitch to the violet of the highest. But suppose the player, instead of gradually shortening his string, to press his finger on a certain point, and to sound the corresponding note; then to pass on to another point more or less distant, and sound its note; then to another, and so on, thus sounding particular notes separated from each other by gaps which correspond to the intervals of

the string passed over. We should then have the exact analogue of a spectrum composed of separate bright bands with intervals of darkness between them. But this, though a perfectly true and intelligible analogy, is not sufficient for our purpose. We must look with the mind's eye at the very oscillating atoms of the volatilised metal. Figure these atoms connected by springs of a certain tension, and which, if the atoms are squeezed, together push them asunder, or if the atoms are drawn apart pull them together, causing them, before coming to rest, to quiver at a certain definite rate determined by the strength of the spring. Now the volatilised metal which gives us one bright band is to be figured as having its atoms united by springs all of the same tension, its vibrations are all of one kind. The metal which gives us two bands may be figured as having some of its atoms united by springs of one tension, and others by a second series of springs of a different tension. Its vibrations are of two distinct kinds. So, also, when we have three or more bands we are to figure as many distinct sets of springs, each set capable of vibrating in its own particular time and at a different rate from the other. If we seize this idea definitely we shall have no difficulty in dropping the metaphor of springs, and substituting for it mentally the forces by which the atoms act upon each other. Having thus far cleared our way, let us make another effort to advance.

Here is a pendulum—a heavy ivory ball suspended from a string. I blow against this ball; a single puff of my breath moves it a little way from its position of rest; it swings back towards me, and when it reaches the limit of its swing I puff again. It now swings further; and thus by timing my puffs I can so accumulate their action as to produce oscillations of large amplitude. The ivory ball here has absorbed the motions which my breath communicated to the air. I now bring the ball to rest. Suppose, instead of my breath, a wave of air to strike against it, and that this wave is followed by a series of others which succeed each other exactly in the same intervals as my puffs; it is perfectly manifest that these waves would communicate their motion to the ball and cause it to swing as the puffs did. And it is equally manifest that this would not be the case if the impulses of the waves were not properly timed; for then the motion imparted to the pendulum by one wave would be neutralised by another, and there could not be that accumulation of effect which we have when the periods of the waves correspond with the periods of the pendulum. So much for the kind of impulses absorbed by the pendulum. But such a pendulum set oscillating in air produces waves in the air; and we see that the waves which it produces must be of the same period as those whose motions it would take up or absorb most copiously if they struck against it. Just in passing I may remark, that if the periods of the waves be double, treble, quadruple, &c., the periods of the pendulum, the shocks imparted to the latter would also be so timed as to produce an accumulation of motion.

Perhaps the most curious effect of these timed impulses ever described was that observed by a watchmaker, named Killicott, in the year 1741. He set two clocks leaning against the same rail; one of them, which we may call A, was set going; the other, B, not. Some time afterwards he found, to his surprise, that B was ticking also. The pendulums being of the same length the shocks imparted by the ticking of A to the rail against which both clocks rested were propagated to B, and were so timed as to set B going. Other curious effects were at the same time observed. When the pendulums differed from each other a certain amount A set B going, but the re-action of B stopped A. Then B set A going, and the re-action of A stopped B. If the periods of oscillation were close to each other, but still not quite alike, the clocks mutually controlled each other, and by a kind of mutual compromise they ticked in perfect unison.

But what has all this to do with our present subject?

¹ The vividness of the colours of the lithium spectrum is extraordinary. It contained a blue band of indescribable splendour. It was thought by many, during the discourse, that I had mistaken strontium for lithium, as this blue band had never before been seen. I have obtained it many times since, and my friend Dr. Miller, having kindly analysed the substance made use of, pronounces it chloride of lithium.—J. T.

They are mechanically identical. The varied actions of the universe are all modes of motion; and the vibration of a ray claims strict brotherhood with the vibrations of our pendulum. Suppose ethereal waves striking upon atoms which oscillate in the same periods as the waves succeed each other, the motion of the waves will be absorbed by the atoms; suppose we send our beam of white light through a sodium flame, the particles of that flame will be chiefly affected by those undulations which are synchronous with their own periods of vibration. There will be on the part of those particular rays a transference of motion from the agitated ether to the atoms of the volatilized sodium, which, as already defined, is absorption. We use glass screens to defend us from the heat of our fires; how do they act? Thus:—The heat emanating from the fire is for the most part due to radiations which are incompetent to excite the sense of vision; we call these rays obscure. Glass, though pervious to the luminous rays, is opaque in a high degree to those obscure rays, and cuts them off, while the cheerful light of the fire is allowed to pass. Now mark me clearly, The heat cut off from your person is to be found in the glass, the latter becomes heated and radiates towards your person; what then is the use of the glass if it merely thus acts as a temporary halting-place for the rays and sends them on afterwards? It does this:—It not only sends the heat it receives towards you, but scatters it also in all other directions round the room. Thus the rays which, were the glass not interposed, would be shot directly against your person, are for the most part diverted from their original direction, and you are preserved from their impact.

Now for our experiment. I pass the beam from the electric lamp through the two prisms, and the spectrum spreads its colours upon the screen. Between the lamp and the prism I interpose this snapdragon light. Alcohol and water are here mixed up with a quantity of common salt, and the metal dish that contains them is heated by a spirit lamp. The vapour from the mixture ignites and we have this monochromatic flame. Through this flame the beam from the lamp is now passing; and observe the result upon the spectrum. You see a dark band cut out of the yellow—not very dark, but sufficiently so to be seen by everybody present. Observe how the band quivers and varies in shade as the amount of yellow light cut off by the unsteady flame varies in amount. The flame of this monochromatic lamp is at the present moment casting its proper yellow light upon that shaded line; and more than this, it casts, in part, the light which it absorbs from the electric lamp upon it; but it scatters the greater portion of this light in other directions, and thus withdraws it from its place upon the screen, as the glass, in the case above supposed, diverted the heat of the fire from your person. Hence the band appears dark; not absolutely, but dark in comparison with the adjacent brilliant portions of the spectrum.

But let me exalt this effect. I place in front of the electric lamp the intense flame of a large Bunsen's burner. I have here a platinum capsule into which I put a bit of sodium less than a pea in magnitude. The sodium placed in the flame soon volatilizes and burns with brilliant incandescence. Observe the spectrum. The yellow band is clearly and sharply cut out, and a band of intense obscurity occupies its place. I withdraw the sodium, the brilliant yellow of the spectrum takes its proper place; I re-introduce the sodium, and the black band appears.

Let me be more precise:—The yellow colour of the spectrum extends over a sensible space, blending on one side into orange, and on the other into green. The term "yellow band" is therefore somewhat indefinite. I want to show you that it is the precise yellow band emitted by the volatilized sodium which the same substance absorbs. By dipping the coal-point used for the positive electrode

into a solution of common salt, and replacing it in the lamp, I obtain that bright yellow band which you now see drawn across the spectrum. Observe the fate of that band when I interpose my sodium light. It is first obliterated, and instantly that black streak occupies its place. See how it alternately flashes and vanishes as I withdraw and introduce the sodium flame!

And supposing that instead of the flame of sodium alone I introduce into the path of the beam a flame in which lithium, strontium, magnesium, calcium, &c., are in a state of volatilization, each metallic vapour would cut out its own system of bands, each corresponding exactly in position with the bright band which that metal itself would cast upon the screen. The light of our electric lamp then shining through such a composite flame would give us a spectrum cut by dark lines, exactly as the solar spectrum is cut up by the lines of Fraunhofer.

And hence we infer the constitution of the great centre of our system. The sun consists of a nucleus which is surrounded by a flaming atmosphere. The light of the nucleus would give us a continuous spectrum, as our common coal-points did; but having to pass through the photosphere, as our beam through the flame, those rays of the nucleus which the photosphere can itself emit are absorbed, and shaded spaces, corresponding to the particular rays absorbed, occur in the spectrum. Abolish the solar nucleus, and we should have a spectrum showing a bright band in the place of every dark line of Fraunhofer. These lines are therefore not absolutely dark, but dark by an amount corresponding to the difference between the light of the nucleus intercepted by the photosphere, and the light which issues from the latter.

The man to whom we owe this beautiful generalisation is Kirchhoff, Professor of Natural Philosophy in the University of Heidelberg; but, like every other great discovery, it is compounded of various elements. Mr. Talbot observed the bright lines in the spectra of coloured flames. Sixteen years ago Dr. Miller gave drawings and descriptions of the spectra of various coloured flames. Wheatstone, with his accustomed ingenuity, analysed the light of the electric spark, and showed that the metals between which the spark passed determined the bright bands in the spectrum of the spark. Masson published a prize essay on these bands; Van der Willigen, and more recently Plücker, have given us beautiful drawings of the spectra, obtained from the discharge of Ruhmkorff's coil. But none of these distinguished men betrayed the least knowledge of the connection between the bright bands of the metals and the dark lines of the solar spectrum. The man who came nearest to the philosophy of the subject, was Angström. In a paper translated from Poggendorff's "Annalen" by myself, and published in the "Philosophical Magazine" for 1855, he indicates that the rays which a body absorbs are precisely those which it can emit when rendered luminous. In another place, he speaks of one of his spectra giving the general impression of reversal of the solar spectrum. Foucault, Stokes, and Thomson, have all been very close to the discovery; and, for my own part, the examination of the radiation and absorption of heat by gases and vapours, some of the results of which I placed before you at the commencement of this discourse, would have led me in 1859 to the law on which all Kirchhoff's speculations are founded, had not an accident withdrawn me from the investigation. But Kirchhoff's claims are unaffected by these circumstances. True, much that I have referred to formed the necessary basis of his discovery; so did the laws of Kepler furnish to Newton the basis of the theory of gravitation. But what Kirchhoff has done carries us far beyond all that had before been accomplished. He has introduced the order of law amid a vast assemblage of empirical observations, and has ennobled our previous knowledge by showing its relationship to some of the most sublime of natural phenomena.

ROYAL INSTITUTION OF GREAT BRITAIN.

Saturday, March 16, 1861.

A Course of Ten Lectures on Inorganic Chemistry, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

LECTURE IX.

(Concluded from page 54.)

Now, these constituents of the atmosphere are not contained in the air in chemical union, but are present in a state of mechanical mixture. The oxygen and nitrogen are not chemically combined with each other, neither are any of the other constituents contained in this table [pointing to the first table given above] with the exception of the ammonia and nitric acid, or carbonic acid. When the air contains, at one and the same time, these substances, they combine, one possessing positive and the other negative energy; in other words, they act as an acid and a base, and exist in the form of a salt; but in all other cases the mixture is a purely mechanical one and not chemical. At one time it was very generally thought—at least many persons imagined—that the air was a chemical compound of oxygen and nitrogen, and even at the present day we sometimes meet with people who entertain this idea. But one of the facts which tells most against this theory is, perhaps, this:—If you agitate a quantity of atmospheric air with recently-boiled water, you will find that the atmospheric air contained in the vessel in which this agitation has taken place becomes richer in nitrogen and poorer in oxygen; that it now contains no longer the same per-centages of these two gases, but several per cent. more of nitrogen than it did before; and it is found also that the water has dissolved a certain quantity of the air according to the proportion in which the two gases, oxygen and nitrogen, exist in that air. You would find, also, on expelling that air again from the water, that it contained more than 30 per cent. of oxygen and less than 70 per cent. of nitrogen. Now, we know of no instance in which a chemical compound can be in this way decomposed by mere solution in a solvent; therefore, it must be a mere mechanical mixture, for the oxygen is washed out from the nitrogen to such an extent as to render the remaining atmospheric air poorer in oxygen. We have also a further proof that the atmosphere is a mixture, by making artificially that mixture. We have here a vessel containing four volumes of nitrogen and one, of oxygen, which is about the proportion, as we have seen, of these gases in the air. Such a mixture has all the properties of atmospheric air, and animals can breathe it for exactly the same length of time as atmospheric air, and a taper can burn in it with exactly the same appearance; and, in fact, it has all the properties, physical and chemical, of atmospheric air. You see no difference in the combustion of this taper when it is lowered into the vessel; it exhibits the same appearance as when burning in the natural atmospheric air, although this is an artificial mixture.

But it may be asked, How is it, if the atmospheric air be a mechanical mixture, that these substances of which it is composed are all so uniformly mixed together, as to give us these almost identical results, as to composition, from whatever source we take our sample of air for analysis? How is it that gases possessing such different specific gravities as nitrogen, oxygen, ammonia, carbonic acid, nitrous acid, and bodies of this kind, do not separate in layers like oil and water? How is it that the nitrogen in the air does not ascend into the higher regions of the atmosphere, and the oxygen accumulate near the surface of the ground, and the carbonic acid form a thinner and distinct layer beneath the oxygen, because carbonic acid has a specific gravity about one-half more than that of air? Oxygen possesses a greater specific gravity than nitrogen, so that one might suppose that we ought to have layers

of these two bodies—in fact, that we ought to have an atmosphere very similar to that which we shall have here if we place two jars, one containing oxygen and the other nitrogen, one above the other, the vessel containing oxygen being placed below, and that containing nitrogen being placed above. There is our jar of nitrogen, and this lower one is the jar of oxygen. I will endeavour to bring them over each other with as little agitation as possible, and then we will remove this plate from between the two gases. [The jars were arranged as stated.] Now, I think we have here these two gases in layers—the nitrogen above, which will, I think, put out our taper, and the oxygen below, you see, which re-ignites it. We do not get this result in the air, for we have, as we have said, the gases uniformly mixed. How is it that this mixture takes place? It has been found that whenever two gases of different specific gravities are placed in contact, even though we place the heavier gas below and the lighter gas above, the two gases will not for any length of time remain in this position; the heavier gas will ascend into the lighter gas above it, and the lighter gas from above will descend into the lower gas. What is termed “diffusion” will take place between those two gases. We have a simple arrangement here which will, I trust, illustrate this fact. Here are two common soda-water bottles which are united by a narrow glass tube, and they have been so united for several hours. The upper of these bottles contained hydrogen, and the lower bottle contained oxygen at the commencement of the experiment, when the bottles were filled some hours ago; so that, you see, we had in the upper vessel a gas which is sixteen times lighter than the gas contained in the lower one; and yet the heavier gas ascends through the narrow glass tube into the upper bottle, and diffuses itself into the lighter gas; whilst at the same time the light gas contained in the upper vessel makes its way, against gravity, downwards through this tube, and mixes with the gas in the lower bottle. By simply applying a light to the mouth of these bottles we shall find that we have an explosive mixture of oxygen and hydrogen which will manifest itself in the ordinary way. [A light was applied to the mouth of the upper bottle, and the contents burnt with a slight explosion.] You see from this that the hydrogen originally in that bottle was obviously mixed with oxygen which must have come up from the lower bottle; and we shall find that some of the hydrogen has gone down into the lower bottle. [A light was also applied to the mouth of the lower bottle with the same result as in the other case.] There also we have an explosive mixture, so that these gases, notwithstanding their very great difference of specific gravity, have yet mixed with each other through this very narrow tube.

Different gases diffuse in this way with different velocities. The lower the specific gravity of the gas, the greater the velocity with which it diffuses. These different velocities have been determined by Professor Graham, and the results are contained in the table which you have here.

Diffusion of Gases.

	Sp. Gr.	Diffusion V Sp. Gr. Volumes.
Hydrogen	0061	2633 457
Ammonia	5898	7681 130
Air	1000	1000 100
Carbonic acid . . .	15239	12345 81
Chlorine	24700	15716 64

I think that this difference in the diffusibility of gases may be clearly shown by a simple experiment. Here is a comparatively narrow glass tube terminating in a wider one, and the upper part of the wide tube is closed with a plug of plaster of Paris about half-an-inch in thickness. We will fill this compound tube with hydrogen by displacement; gradually withdraw this gas delivery tube and plunge the lower and open end of the compound tube into a coloured liquid, and now we shall have the hydrogen

rushing out and the air rushing in through this plug; but the hydrogen rushes out more rapidly than the air can get in, and consequently we have a rarefaction produced in the interior; and you see the effect of it in the rising of the coloured liquid, which is ascending very rapidly into the narrow tube, thus showing that the hydrogen is diffusing through that plaster of Paris plug much more rapidly than the atmospheric air, which is quite in accordance with the numbers in that table. Here is another experiment which illustrates the same thing to some extent. Here is a beaker, containing atmospheric air, which has been closed by means of very thin caoutchouc, and it is surrounded by a jar containing hydrogen which passes into the beaker to a much greater extent than the air gets out of the beaker. The hydrogen passes into the glass more rapidly than the air gets out, and the consequence is that we have a protuberance of the membrane which was at first perfectly flat. Here [exhibiting a similar beaker] we have the experiment inverted. This glass vessel was filled with hydrogen, and covered with a caoutchouc membrane. You see how the hydrogen has got out of the vessel more rapidly than the atmospheric air got in, and therefore this membrane is pressed into the jar to a very great extent.

Diffusion is one mode, then, by which the constituents of the atmosphere are kept mixed together, or prevented from separating into layers at all events. Then the mixture is rendered still more uniform, and any accumulation of gaseous matter at one particular place is rendered almost impossible, by atmospheric currents. I can only allude very slightly to the chief of them, namely, the trade winds, which, as you are aware, extend somewhat more than 30° on each side of the equator, and by means of which the atmospheric air from the temperate regions is carried into the torrid zone, and is then brought back again, by an upper current in an exactly opposite direction, into the colder regions. In this way there is a constant interchange of air between the Temperate, and even Polar regions, and the Tropics; and thus the whole atmosphere is kept in a state of constant mixture by the action of these trade winds.

But we have various operations going on in the atmosphere which must have a tendency, if they were not counteracted, to produce a gradual and permanent change in the comparative amount of each constituent. We have seen that combustion and respiration produce considerable quantities of carbonic acid gas; decay and putrefaction produce also immense quantities of the same gas. In the course of a single day by the combustion and respiration going on in London alone there are given into the atmosphere of our city no less than 150,000,000 cubic feet of carbonic acid. When we consider the vast extent to which these processes are going on all over the inhabited portion of the surface of the globe, we might be led to expect that the quantity of carbonic acid would be gradually increasing in the atmosphere; but there is another operation going on simultaneously, which tends in the opposite direction. This operation is the function of plants in taking carbonic acid from the air and restoring the oxygen of that carbonic acid. Just as animals, in breathing, take in the oxygen of the air, and give out carbonic acid, so plants take in by their leaves, which are really also their lungs, this very carbonic acid, and give out oxygen again in the same volume as it is contained in the carbonic acid which they absorb. Thus, whilst respiration, combustion and decay are sending into the air immense quantities of carbonic acid, all the green parts of vegetables are absorbing that carbonic acid, and restoring its oxygen into the atmosphere. Combustible substances remove oxygen from the air in forming carbonic acid, and the plants restore the same amount of oxygen back again into the atmosphere. By the simultaneous action of these two classes of processes, something like an equilibrium in the quantities of oxygen

and carbonic acid present in the atmosphere at any one time is produced.

You will perceive from what I have just said that both the oxygen and the carbonic acid contained in the air have very definite functions to perform; but we have hitherto seen no use for the nitrogen contained in the atmosphere. The nitrogen would appear, if we look at it only superficially, to be quite a useless element. If the nitrogen were removed from the air, the same volume of atmospheric air would then contain exactly the same amount of oxygen as it does at the present moment, because the oxygen would spread itself out throughout the same space as it now occupies; therefore, if no nitrogen were present, you would have only the same amount of oxygen in a cubic yard of air as you have at the present moment; but still the relation of the atmosphere to combustion, and, no doubt, to respiration also, would be very different from what it is at present. In all cases of combustion in air the nitrogen takes up large quantities of the heat generated, and keeps down the temperature of the burning body, and this, in fact, prevents the combustion from becoming altogether uncontrollable. We have seen the difference between the burning of charcoal, for instance, and phosphorus, and other bodies, in pure oxygen and in atmospheric air; but you may say that if the oxygen were rarified in this way, the combustion would not proceed more rapidly or with greater intensity than it does when mixed with four volumes of nitrogen. We will just try this. Here is a receiver containing air which we will extract, and we will then fill the vessel with oxygen; when we have done that, we will pump out of it four-fifths of the oxygen that it contains, so as to leave in that receiver only the same amount of oxygen that there would be originally present in it when filled with air. Now we are admitting into that receiver a quantity of oxygen. [The jar having been filled with oxygen, the air-pump was applied until the oxygen was rarified to a pressure of six inches.] We have there a pressure of only one-fifth of the atmosphere, or six inches of mercury. We have an arrangement in the inside of the receiver by which we can ignite a piece of phosphorus, and then you will see whether the phosphorus burns with anything like the same brilliancy as in oxygen at the ordinary pressure. Now that phosphorus is burning there in the oxygen which is only of the same density as the oxygen in atmospheric air. The result is strictly the same, and the light is quite as brilliant as if we were burning the phosphorus in oxygen of the ordinary density at the full pressure of the atmosphere. Thus it is the nitrogen, and the nitrogen alone, which reduces the temperature of combustion, and renders the ordinary combustion controllable. We might also show you by a similar experiment with watch-spring that the pressure of the oxygen does not affect the combustion, but we will forego that experiment, as it would occupy too much time.

Then, again, the atmospheric nitrogen reduces the rate of evaporation, by putting an additional pressure upon fluids. We should have water boiling at a temperature of about 150° , or even below that, if no nitrogen were present in the atmosphere; and the effect of that would be that we should have a far greater quantity of aqueous vapour in the air than we have at the present time. It is true that when saturated the atmosphere would not contain more vapour than it does now, but the point of saturation would be attained in far less time, and the atmosphere would be at all times, quite, or almost, completely saturated with aqueous vapour, if no nitrogen were present in it. I will show this by placing a vessel of warm water, at a temperature of about 150° under the receiver of the air-pump, and then exhausting the air to one-fifth the present pressure. The water is so little heated that I can bear my finger in it for a short time. When we reduce the pressure to the point I have mentioned, I think you will see that that water will boil. [The experiment was

Now these organic substances have, undoubtedly, a most important influence upon the health of the inhabitants; and we have invariably seen that where an improvement has been fairly tried, in respect to the drainage of towns, which has an important effect upon the air, it has had a most remarkable influence in reducing the mortality in those towns. Here is an instance upon this table showing such a result in the case of Croydon:—

Mortality per Thousand at Croydon.

1853	.	.	.	.	.	28
1854	.	.	.	.	.	26
1855	.	.	.	.	.	20
1856	.	.	.	.	.	17
1857	.	.	.	.	.	16

In Croydon, in the year 1853, the drainage was excessively bad, and at that time the mortality there was 28 per thousand per annum. In 1854 some little improvement was made—in fact, the drainage works were commenced, and the mortality was slightly less. In the year 1857, when the works were completed, the mortality was reduced to 16 per thousand, and has remained about that down to the present time. We may, therefore, regard the difference in the number of lives between 16 and 28 as absolutely saved by a better sewerage in that place. Here again we have similar results in the case of Ely:—

Annual Mortality per Thousand in Ely.

From 1843 to 1849	.	.	.	.	.	26
„ 1851 to 1855	.	.	.	.	.	20
1856	.	.	.	.	.	17
1857	.	.	.	.	.	17

You have again in another table a representation of the comparative mortality in many of our large towns:—

Of 1000 Persons Living in the Following Places there Die Yearly:—

In Liverpool	.	.	.	.	.	33
Manchester	.	.	.	.	.	31
Birmingham	.	.	.	.	.	27
London	.	.	.	.	.	24
Small towns and villages	.	.	.	.	.	20
Estimated normal death-rate	.	.	.	.	.	11

The estimated normal death-rate is only 11 persons in 1000 annually. From these tables you will be enabled to judge of the influence upon the atmosphere of these sewer emanations. While the gases escape as they do from the sewers into our atmosphere, they will undoubtedly exercise a most insalubrious effect upon the localities where they are let loose, and there cannot be a doubt that all improvements by which the gases are confined within the sewers, or are not allowed to escape into the atmosphere without passing through charcoal filters, such as are now being applied to some of the London sewers, would very considerably reduce the mortality of our large cities.

NOTICES OF PATENTS.

Treating Coal, and other Bituminous Materials, and Peat, for the Purpose of Obtaining Solid and Liquid Hydrocarbons. W. M. WILLIAMS.

THIS specification refers to an improved method of distilling coal and other bituminous minerals, under conditions of increased pressure, whereby the yield of paraffin, paraffin-oil, and other liquid and solid hydrocarbons is considerably augmented, as compared with processes of distillation at ordinary pressures, when the production of illuminating gas is the chief object of manufacture. The treatment of peat by the same process constitutes an additional claim under this patent, and is said to furnish similar products.

The process here described may be cited as an interesting example of the action of mechanical forces in determining the molecular arrangement of compound bodies. In the instance of the destructive distillation of coal, whether the hydrocarbons take the form of paraffin or illuminating gas, depends entirely on the physical conditions operating at the moment of production; these substances are but allotropic modifications of the same chemical compound, which, although identical in constitution, exhibit in their

general characters widely different properties. In this respect the present specification bears a remote physical resemblance to the process of Mr. Young for producing paraffin from coal by distillation conducted at low temperatures.

Coating Metals and Metallic Alloys. W. BAGLEY and W. MINCHER, Birmingham. (Not proceeded with.)

FOR the purpose of coating metals, such as iron or steel, with lead, or a metallic alloy composed of lead with a small quantity of copper, the inventors proceed to clean the surfaces of the original metal firstly by the process of scaling, and afterwards by immersion in dilute hydrochloric acid. When thus prepared, the sheet iron is subjected to the action of a mixed solution, containing chloride of lead in combination with the hydrochloric solution of arsenious acid; there it remains until a coating both of lead and arsenic is formed by reduction of these metals on the iron surface. Acting as a flux, this coating enables the iron to take lead freely, when the plate is afterwards dipped into a bath containing the latter metal in a molten state. The patentees prefer, however, to employ for the final coating, instead of pure lead, an alloy of lead with a small proportion of copper; and the article (plate or otherwise) is removed after dipping, cooled, and finished in the ordinary manner.

A practical trial would be necessary before a precise opinion could be given in regard to the necessity for employing an arsenical solution of so volatile a nature as that here recommended. Considering that arsenic plays so small a part in the ultimate composition of the metallic coating, it would be highly desirable in experimenting with this process to endeavour to avoid altogether the use of a poisonous agent, the fumes of which would certainly be prejudicial to the health of the workmen engaged.

Coating Metals and Alloys of Metals. W. BAGLEY and W. MINCHER.

THE patentees secured provisional protection, but did not proceed with another suggestion for the same object as the last. This consists in a preliminary preparation of the iron surface as before, and immersion in a solution of chloride of zinc; then, by galvanic agency, depositing upon the iron a coating of metallic zinc, which serves to facilitate the attachment of the lead when afterwards the article is dipped into a bath of molten lead, employed pure, or previously alloyed with a small proportion of copper.

It is a common practice to employ zinc for coating iron prior to its receiving a thicker surface of lead; and the chloride of zinc is also frequently used as a flux. The suggestion of employing an electro-deposit of zinc for this special application appears to be novel, but the advantage of the new process, especially in regard to expedition, does not seem manifest.

Insulating the Conducting Wires used for Telegraphic Purposes. W. HIRSCH. (Not proceeded with.)

THIS specification refers to a method for securing the more perfect insulation of telegraphic wires by enveloping them in coils of spun glass, and afterwards filling up the capillary interstices between the vitreous fibres with resinous, tarry, or other non-conducting fusible material.

Glass, although one of the best insulating materials known, would, at the same time, we fear, be one of the most expensive. In the condition of spun filaments, its cost of production would be considerably augmented; and, unless it be proved that the resinous coating would itself afford additional protection, it is very questionable whether glass, in this state of division, could resist for any length of time the corrosive action of water.

An Improved Method of, and Machinery for, Amalgamating and for Effecting the Separation of Gold from Earthy and other Matters containing the same. B. G. SLOPER. (Not proceeded with.)

THIS invention refers principally to a mechanical contrivance for assisting the action of the mercury in the process of extracting gold from crushed quartz and other rocks containing it. An Archimedean screw, and another working vertically, are kept in rotation by suitable machinery, and the apparatus is in part surrounded with a steam jacket, so that, by a more elevated temperature, the mercury may have its amalgamating powers to some extent augmented.

Preserving Organic Substances. W. RATTNAY, Aberdeen.

THIS patent refers to the application of sulphurous acid and its compounds with the alkalies and alkaline earths, as means of preventing the decomposition or decay of sundry vegetable and animal substances.

Considering that these agents have long been employed for checking the fermentation of beer, in the drying and preservation of hops, and in a few similar instances with well-tried efficacy, there is little doubt that the use of sulphurous acid for the purpose contemplated would be equally successful.

Filters. W. CLARK. A Communication. (Not proceeded with.)

THIS specification describes the construction of a portable filter. It consists of an india-rubber bottle divided into upper and lower compartments by a porous plate or diaphragm of filtering material. Both extremities are provided with stop-cocks, that above being connected with the water supply-pipe. When in use the filtering bag or bottle is necessarily kept distended, so that the apparatus requires to be supported in a light frame work, but when dismantled the india-rubber collapses upon the porous diaphragm, and the whole arrangement occupies very little space.

CORRESPONDENCE.

Phosphorus Matches.

To the Editor of the CHEMICAL NEWS.

SIR,—In the *Chemical News* of July 27 there is a description of a well-corked bottle, coated internally with phosphorus. "But," says Mr. G. Gore, "It was not until 1833 that it (the phosphorus) was successfully applied (for lighting matches)." Now, Sir, there lived in Dublin, on the Quay, near the Four Courts, a chemist, who made his fortune in 1816 by the manufacture of precisely such bottles as Mr. Gore describes, and which never failed to give a light. William Kertland was the name of that chemist, and there are still living those who remember to have seen him in their youth jovially spending the Sunday evening at Quinn's Bray after a ramble through the Daryle at Powerscourt, so prosperous was his business.

I am, &c.

ZAMIEL.

Salts of Manganese.

To the Editor of the CHEMICAL NEWS.

SIR,—Referring to an inquiry in a recent Number of the CHEMICAL NEWS, I beg to state that I am manufacturing "solid chloride of manganese," and should be obliged if you would inform your correspondent of this. I will furnish him with particulars on application.

I am, &c. B. W. GERLAND.

Newton-le-Willows.

To the Editor of the CHEMICAL NEWS.

SIR,—I can supply your correspondent with any quantity of chloride of manganese, pure or commercial, crystallised or in large lumps. I am, &c. WM. LORBERG.
Queen Street, Bermondsey, S.E.

On the Adulteration of White Lead.

To the Editor of the CHEMICAL NEWS.

SIR,—I am glad to see in your last Number of the CHEMICAL NEWS an *exposé* of the frauds in white lead. Some time ago I analysed a portion of white lead that came from a wholesale colour house near Cheapside, and it was adulterated 30 per cent. Shortly afterwards I had a sample sent me for analysis that came from a large manufacturer not far from Holborn Hill as "extra superfine," and it was adulterated 32 per cent. In both instances the principal of the firm admitted that they were adulterated, but excused themselves by saying that it was a mistake of the warehousemen.

I had occasion to analyse some linseed oil that came from a City crusher, and it was mixed with 20 per cent. of resin oil.

Trade has now become a system of adulteration, and that manufacturer who is the cleverest at adulteration is the one who makes the largest fortune and secures the greatest trade.

I am, &c.

GEO. JAS. JOHNSON
258, High Street, Chatham, and Beacon Hill, Luton.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Perchromic Acid.—Aschoff (*Journal für prakt. Chemie*, Bd. lxxxi. s. 401) confirms the existence of a definite acid Cr_2O_7 , formed when binoxide of nitrogen acts on a dilute solution of bichromate of potash. The blue compound formed in this reaction is, as our readers know, soluble in ether, and when the ethereal solution is shaken with a dilute solution of potash added in such a quantity that the blue colour is hardly apparent, the aqueous solution which separates is of a deep violet-brown colour, and perfectly neutral. It becomes again blue on the addition of an acid, but an excess of potash completely decomposes it, just as in the case of the acid Mn_2O_7 . The colouring power of perchromic acid is immense, a decigramme being sufficient to give a deep blue colour to 500 cub. cents. of water. The author could not obtain a definite salt with the acid.

Permanent Source of Ozone.—Boettger says (*Zeitschrift für Chem. und Pharm.*, Bd. iii. s. 718) that a mixture of two parts of permanganate of potash and three parts of sulphuric acid forms a pasty mass, which will continue to give off ozone for several months.

Preparation of Permanganate of Potash.—Boettger recommends the following process, (*Ibid.*)—Fuse together in an iron crucible, 4 parts of hydrate of potash, and 2 parts of chlorate of potash, and when oxygen begins to be evolved remove the crucible from the fire, and stir in gradually one part of peroxide of manganese. Heat again until the mixture solidifies, after which boil it with 80 parts of water, and then pass carbonic acid until the liquid becomes red. The solution is now decanted, filtered through gun-cotton, evaporated to one-half and set aside to cool, whereupon large crystals of the permanganate are obtained.

Artificial Chalybeate Water.—Hauer points out (*Journal für prakt. Chem.*, Bd. lxxxi. s. 391) that reduced iron dissolves with facility in a solution of carbonic acid, the solubility increasing, of course, under pressure, and being diminished by the presence of alkaline carbonates

in the water. Our readers ought to know, however, that the above way of making chalybeate water has been patented in England for a year or more.

II. ORGANIC CHEMISTRY.

Purification of Acetic Ether.—The following method of rectifying acetic ether is given by Engelhardt (*Zeitschrift für Chem. und Pharm.* Bd. iii. s. 618): The rough product contains free acetic acid and alcohol. In consequence of the presence of the latter, it is soluble in an equal volume of water; but when pure, it requires at least seven times its volume to dissolve. The author's process is based on this fact. He begins by neutralizing the acetic acid with calcined magnesia, he then dilutes with an equal volume of water, and afterwards adds sufficient common salt to make a saturated solution. When no more salt dissolves, the whole is shaken up, and then allowed to rest, whereupon the mixture separates into two layers, the lower of which is a saturated solution of common salt in dilute spirit, and the upper acetic ether nearly anhydrous (0.89) and quite pure. No further rectification is necessary.

New Compound by the Action of Hydrogen on Nitrobenzine.—Jumel (*Bulletin de la Société Chimique de Paris*, No. II., p. 47), passed simultaneously dry hydrogen and the vapour of nitrobenzine over platinum black contained in a porcelain tube and heated. At first white vapours were copiously produced, then these ceased and a yellowish-brown oil condensed and fell to the bottom of the water in the receiver. After some time the production of this oil stopped, very heavy yellow vapours passed, and then a large quantity of thick, black oil condensed. In several experiments the same phenomena presented themselves in the same order. The yellow oil dissolved in acetic acid, the solution treated with hypochlorite of lime gave a dirty violet-red colour like wine lees; bichromate of potash produced no colour. Tested with the hypochlorite and without acid, it gave a blue colour, dirty at first, but which deepened in time, and eventually looked like an alkaline solution of sulphate of copper. This blue colour, the author found, was reddened by acids and restored by alkalis just like litmus. The blue matter is soluble in water and alcohol, and dyes, but the colour washes out. The black oil obtained, the author found to be only a product of the decomposition of vapour of nitrobenzine heated to about 400° C.—for after a time the platinum becomes covered with carbon and does not act.

Veratric Acid = $C_{10}H_{10}O_8$, according to W. Merck, yields with strong nitric acid yellow nitro-veratric acid $C_{10}H_7NO_{12}$, which is soluble in water, crystallizes from alcohol and yields binitroveratric acid with more NO_2 . By heating moderately with 3 parts of baryta, veratrol = $C_{10}H_{10}O_4$ is obtained, which has an aromatic odour, crystallizes at 15° (59° F.), possesses the specific gravity of 1.086, boils between 202° and 205° (396° to 401° F.); it yields with fuming nitric acid nitro- and binitroveratrol, and with bromine bibromoveratrol = $C_{10}H_6Br_2O_4$.—*Annal. der Ch. und Ph.* xxxii. 58—62.

III. ANALYTICAL CHEMISTRY.

Estimation of Iodine in Tincture.—Ranwez (*Polytech. Notizblatt*, Bd. xvi. s. 47) shakes the tincture with a known weight of granulated zinc. When the solution is colourless, he separates the metal that remains, dries, and weighs it. The amount of iodine is calculated from the loss. Pure zinc must, of course, be employed.

IV. TECHNICAL CHEMISTRY.

Extraction of Silver from Galena.—Sulphide of silver and chloride of lead mutually decompose when fused together. The reaction has been applied with success to the extraction of silver from galena. The galena is

mixed with one per cent. of chloride of lead and ten per cent. common salt, and the mixture is fused. Chloride of silver is formed, and, together with the chloride of sodium, swims on the surface, forming, when cold, a crystalline crust, which is easily separated. The crust will contain an excess of chloride of lead. The reduction of the metals may be proceeded with in the ordinary way.—*Polytech. Notizblatt*, s. 95.

MISCELLANEOUS.

Practical and Theoretical Chemistry.—The labours of physiological chemists have pretty well settled the general principle, that the material by which our bodies are sustained, may be conveniently arranged under the heads of blood-producing food, and food which is principally consumed, during the process of respiration, in generating animal heat. The blood-producing food, consisting chiefly of albumen, fibrin and casein, contains nitrogen; while the heat-producing food is devoid of that element. Very complicated formulæ are assigned to the blood-producing principles, giving, according to some authorities, more than one hundred equivalents to two of their elements, namely, carbon and hydrogen. Such formulæ cannot be supported by analysis with any show of probability. Nevertheless, they are chemists, who take these improbable formulæ as proved; and venture to trace the transformations which the blood-producing principles of the food undergo, during their conversion into blood. Thus, they say, that casein, with a certain proportion of water, may yield blood-albumen and chondrin, the latter being the principle of cartilage; and, again, that two equivalents of albumen and two of water are equal to one equivalent of blood-fibrin, one equivalent of choleic acid, and one equivalent of gelatin. The equations here given are true equations, on the assumption that the composition of the substances concerned is correctly represented; but this assumption is wholly gratuitous. Admitting, however, that the analyses are correct, can it be believed that equations like these represent the truth of nature? These chemists, drawing on their fancy, do not hesitate to make any transformation that may suit their theories. If they have too much oxygen to suit their views, oxygen is alleged to be given off; if there is present too much of both oxygen and hydrogen, then water is formed; and, if carbon is redundant, they do not hesitate to say that the portion in excess is removed, in the form of carbonic acid, by the oxygen of the air! This scientific facility reminds us of an anecdote which is related of one of our Commissioners of Patents, who was in office about the beginning of the present century. He was a man of general information, but had no pretensions to a knowledge of science; and, in his own opinion, everything was easy to accomplish. Being simple minded and credulous, he was easily imposed upon. A wag applied to him for a patent for making boards out of sawdust. "Oh! my friend," said the Commissioner, "that art has long been known, and is very easy." "But," said the applicant, "I fear, sir, you do not exactly understand my purpose. My invention consists in making pine boards out of oak sawdust." "Oh! is that it," rejoined the Commissioner; "but that is very easy also, for you have only to add a little turpentine!"

ANSWERS TO CORRESPONDENTS.

W. X. Y.—The sample of oil which you have sent is largely adulterated with olive oil, and is not worth a quarter the sum you name.

Y. C. Bell.—Steel beams of balances can be protected from injurious fumes of the laboratory by being lacquered, or better still by being electro-gilded. For a small blast furnace apply to Griffin and Co., Bunhill Row.

J. D. Ferriss.—We will inquire, and communicate with you.

VOL. IV. No. 88.—August 10, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

*On the Exact Separation of the Ethyl Bases,¹
by M. CAREY LEA, Philadelphia.*

It has been known for some time that when ammonia was acted upon by the halogen ethers, the ethylamine produced was always accompanied by a variable quantity of the secondary and tertiary ethyl bases and the ammonium base, and I have shown that the same is the case with respect to the secondary and tertiary ethyl bases in the reactions of oxy-ethers. The ammonium base I have not looked for, but it is, doubtless, present also. The primary, secondary, and tertiary bases resemble each other so closely in their properties, that their separation is attended with great difficulty, and has generally been effected by the different solubilities of their chloroplatinates.² I find, however, that it may be accomplished with great ease by means of picric acid. The picrates of the different bases exhibit the most opposite degrees of solubility, the picrate of triethylamine rivalling the picrate of potash in insolubility, while that of diethylamine is soluble to an almost unlimited extent in water, alcohol, and ether, without being in the least deliquescent. Its affinity for ether is so great that its concentrated ethereal solution will remain exposed to the atmosphere for days in a syrupy condition, gradually crystallising on the surface, and eventually all through, to a radiated mass. Between these two extremes the picrate of ethylamine occupies an intermediate position, and the differences of solubility are so well marked as to render the separation perfectly easy in the manner to be indicated below.

1. Separation of the Mixed Bases from Ammonia.

This has been generally directed to be done by treating the mixed hydrochlorates either with absolute alcohol, or with a mixture of strong alcohol and ether, whereby the sal ammoniac is supposed to be left undissolved.

This process I have always found to the last degree unsatisfactory, and necessarily so; for if absolute alcohol be allowed to stand over sal ammoniac in powder for a time and then be evaporated in a watch-glass, a certain quantity of sal ammoniac will be deposited, and the same is true of a mixture of strong alcohol and ether. By operating on the ammonias in the form of sulphates, a much more satisfactory result is obtained. For this purpose the mixture as poured out from the pressure-tube is treated with a sufficient quantity of pure sulphuric acid to displace the nitric acid (or if bromide or iodide of ethyl have been employed, the bromhydric or iodyhydric acid), and the solution is evaporated as far as possible at a temperature of about 250° F. The paste

mass is exhausted with strong alcohol, the alcoholic solution is evaporated as far as possible at the same temperature, and the residue exhausted with a small quantity of absolute alcohol. Two exhaustions at least are necessary, even when absolute alcohol is used the first time. In this way a satisfactory result is obtained, which cannot be accomplished with the chlorhydrates.

2. Separation of the Mixed Bases from each other.

TRIETHYLAMINE.

After being completely freed from ammonia, as above described, the mixed sulphates were distilled with caustic potash, in the usual way, and the bases were saturated with crystallised picric acid. Sufficient heat was applied to re-dissolve the precipitate which formed toward the close of the saturation, and the hot (not too concentrated) solution allowed to crystallise. The first crop of crystals thus obtained were purified by several re-crystallisations, the chlorhydrate of the base was formed, and from this the chlorplatinat, which was obtained in large and beautiful crystals. The platinum salt was analysed.

·4858 grammes substance gave ·1567 platinum,

Per cent.

This corresponds to 32·26

Chloroplatinat of triethylamine contains 32·23.

The close correspondence of the result with the number given by theory indicates the perfect purity of the triethylamine. Its proportion is but inconsiderable compared with that of ethylamine and diethylamine, and it is chiefly contained in the first portion of the gaseous products which pass over in the distillation with caustic potash.

Picrate of triethylamine crystallises in delicate yellow needles, which dissolve sparingly in cold water and alcohol, abundantly in hot. The decrease of solubility in an aqueous or alcoholic solution as it cools is very sudden, so that a hot solution deposits almost the whole of the salt as it begins to cool. Placed on platinum foil and gently heated, it melts, turns first red, then black, at the same time boiling up, takes fire, and leaves a residue of charcoal.

ETHYLAMINE.

After the least soluble salt had been removed in the manner just described, the mother-water deposited another crop of crystals, which were purified by repeated re-crystallisation, the chlorhydrate of the base was formed, and its chlorplatinat was analysed.

·4429 grammes substance gave ·1728 platinum.

Per cent.

This corresponds to 39·02

Chloroplatinat of ethylamine contains 39·29.

Picrate of ethylamine presents great differences of appearance according to accidental circumstances. When first crystallising out of the mixed solution, it usually forms groups of short, brown prisms, adhering to the bottom of the basin. If these be re-crystallised, we obtain long, yellow, flattened prisms and laminæ, extending in every direction through the liquid; few substances

¹ American Journal of Science and Art.

² Dr. Hoffman has lately described an elegant mode of separation, differing, however, entirely from that here proposed,—viz., by means of oxalic ether.

exhibit more beautiful crystallisations. A dilute alcoholic solution often deposits flat prisms, bevelled at the extremities, and sometimes hexagonal plates.

In solubility in water this substance approximates to the picrate of ammonia, to which, after it has been subjected to repeated re-crystallisations, it bears considerable resemblance in appearance.

DIETHYLAMINE.

After the picrate of ethylamine has been for the most part removed, the mother-waters exhibit a curious phenomenon, which greatly simplifies the further purification of the diethylamine salt left in solution. When these mother-waters have been a little reduced by spontaneous evaporation, or by a gentle heat, the liquid spontaneously separates into two layers, a pale yellow, lighter, and a dark brown, heavier. The evaporation is continued until the heavier layer constitutes rather more than half of the whole, and then the two layers are separated, either at once by a separating-funnel, or ether may be added and thoroughly shaken up, when the brown layer dissolves in the ether and rises to the top. After separation it is allowed to crystallise and is once or twice re-crystallised from a small quantity of ether, by which it is obtained quite pure. A specimen was converted into chlorhydrate and then into chlorplatinate, and gave the following results on analysis:—

*3884 grammes substance gave	1377 platinum.
	Per cent.
This corresponds to	35.45
Chloroplatinate of diethylamine should contain	35.45.

It appears, therefore, that the salt obtained in the above-described manner is perfectly pure.

Picrate of diethylamine, without being deliquescent, is soluble to almost any extent in water, alcohol, and ether. By spontaneous evaporation, it crystallises in a radiated mass: Sometimes at the bottom of the vessel beautiful transparent brown-yellow crystals form, which belong to the monoclinic system. Combination observed $\infty P \infty$, [$\infty P \infty$], ∞P , ∞P , $+ P$, and a clinodiagonal doma.

The approximate proportions in which the different ethyl bases were produced by the reaction here made use of were, perhaps, ten per cent. of triethylamine, thirty or forty of diethylamine, and fifty or sixty of ethylamine.

The method here described gives with facility a very exact separation of these bases. The only precaution necessary to be observed, especially in operating on small quantities, is, that the solution must not be too concentrated at the outset, otherwise the picrate of triethylamine will be mixed with picrate of ethylamine. But the delicate needles of the former are easily distinguished from the broader ones and prismatic crystals of the latter, and two or three re-crystallisations suffice to separate them completely.

I feel assured that picric acid will be found to be a most valuable re-agent in effecting separations of cognate organic bases. It may be doubted if there exists any other acid whose salts, taken as a whole, exhibit so marked a tendency to ready crystallisation, and the great differences in the solubility of picrates of allied bases adds, as in the foregoing example, to the value of this acid in effecting separations between them.

On Didymium, Lanthanum, Cerite, and Lanthano-Cerite,
by R. HERMANN.

R. HERMANN has studied the preparation of the oxides of cerium, lanthanum, and didymium. These oxides

are still often separated, according to Mosander's process, with diluted nitric acid, and crystallising the sulphates of lanthanum and didymium. The substances thus prepared are, however, never perfectly pure.

After treating the oxides with dilute nitric acid, the undissolved protoxide of cerium is best purified by solution in sulphuric acid, mixing the concentrated solution with much water, and then heating, by which means perfectly pure sulphate of cerium is separated.

In order to purify the oxides of lanthanum and didymium perfectly, advantage may be taken of the circumstance that oxide of lanthanum is a more powerful base than oxide of didymium.

With this object the two substances are first separated by the crystallisation of their sulphates. This operation is facilitated by the fact that sulphate of lanthanum is more difficultly soluble than sulphate of didymium. From a concentrated solution of the two salts prepared in the cold, sulphate of lanthanum separates out first on the application of heat, while the sulphate of didymium remains for the most part in solution. This solution is then evaporated at the temperature of the air to dryness. A mixture is thus formed of crystals of sulphates of didymium and lanthanum. When these are treated with cold water, the sulphate of didymium is dissolved in preference, while the sulphate of lanthanum, which, in the crystallised state, is very difficultly and slowly soluble in a concentrated solution of sulphate of didymium, remains to a great extent behind. This solution of sulphate of didymium is again suffered to evaporate to dryness, and the sulphate of didymium is once more dissolved in cold water. This operation must be repeated as long as sulphate of lanthanum continues to separate. Finally, by these crystallisations tolerably pure sulphates of lanthanum and didymium are obtained.

In order to purify these salts completely, a portion of each solution is precipitated with ammonia, and the precipitates well washed. These precipitates are then mixed with the remaining portion of the same salts and allowed to remain a few days at a gentle heat, with frequent stirring.

If impure sulphate of lanthanum has been so treated, the basic sulphate of lanthanum precipitates the sulphate of didymium still present in the solution completely, and there remains nothing but sulphate of lanthanum in solution, which can be crystallised by the evaporation of the solution.

If, on the other hand, impure sulphate of didymium has been employed, the basic sulphate of lanthanum dissolves perfectly in the liquid, and basic sulphate of didymium is precipitated. After a few days the sediment will consist of nothing but pure basic sulphate of didymium. This may be collected on a filter, dissolved in sulphuric acid, and crystallised.

Examination of some Didymium Compounds.—The compounds of didymium were examined by Mosander, and subsequently very fully by Marignac. Marignac fixed the atomic weight of didymium at 600¹, according to the author it is 593.5.

Oxide of Didymium, obtained by precipitating the sulphate with oxalate of ammonia, heating the oxalate to redness, in the presence of air, and subsequently strongly heating the peroxide so obtained in a covered crucible, appears as white pieces with an earthy fracture, sp. gr. 6.54. By treating peroxide of didymium in a

¹ The oxygen = 100 scale is adopted throughout this paper.

current of hydrogen, it forms white pieces of the texture of the peroxide. It consists of

Di 85.58
O 14.42

100.00

Peroxide of Didymium, prepared by heating nitrate of didymium in the air, forms a silky-looking, spongy mass of a brown colour. By heating the oxalate in the air, with constant stirring, it is obtained in the form of a chestnut-brown powder. Heated in a current of hydrogen, it alters its colour immediately from brown to white, water being formed at the same time. On the other hand, the white oxide immediately becomes brown when heated in the air.

If peroxide of didymium is heated in a covered platinum crucible, so that the crucible lies deep in the flames, and all access of atmospheric air be thus cut off, the action of the deoxidising gases of flame, however, being facilitated, a perfect reduction to the state of white oxide takes place. If the peroxide be dissolved in the oxygen acids, it is reduced with evolution of oxygen to the white oxide. With hydrochloric acid it evolves a small quantity of chlorine.

The composition of peroxide of didymium may be very accurately determined; if a weighed quantity be treated in a close vessel with the solution of the iodide of potassium in diluted hydrochloric acid, and then be allowed to dissolve perfectly, iodine is thus set free as an equivalent of the oxygen which the peroxide contains more than the protoxide. With standard solutions of hyposulphite of soda and iodine, the quantity of iodine set free may be determined. In this way 100 parts of peroxide of didymium set free 7.070 of iodine, which expresses 0.446 oxygen. According to this, the composition of peroxide of didymium may be expressed by the formula $\text{Di}_{23}\text{O}_{33}$:—

Di	85.20	32 =	18992.0	85.19
O	14.80	33 =	3300.0	14.81
	100.00		22292.0	100.00

Attempts to prepare a peroxide of didymium containing a greater proportion of oxygen met with as little success with the author as with Marignac. When a previously-fused mixture of nitrate of didymium and nitrate of potassium was projected into a fused mixture of chlorate of potassium and hydrate of potassium, a brown oxide was obtained, which by the iodine test yielded exactly as much iodine as the peroxide prepared by heating the nitrate of didymium. Also, when peroxide of didymium was treated with a quantity of nitric acid insufficient for complete solution, an oxide remained behind of the same composition as it was before this treatment. Peroxide of didymium, as well as the protoxide, dissolves easily, and with evolution of heat, in sulphuric, nitric, hydrochloric, and acetic acids, and forms with these acids rose-red solutions, which are precipitated white by phosphoric and oxalic acids, and by ferro-cyanide of potassium. With the help of the blow-pipe the oxides of didymium form with borax, both in the outer and inner flame, rose-coloured glasses. The oxides of didymium are dissolved by phosphates with greater difficulty than by borax. A glass is formed in this case that easily becomes turbid from a white deposit; it shows, however, when strongly saturated, a distinct rose coloration. The blue colour mentioned by Mosander was only remarked by the author when the oxide of didymium contained cobalt.

(To be continued.)

On the Production of Graphite by the Decomposition of Cyanogen Compounds, by Dr. P. PAULI.

THE mother-liquors obtained from the evaporation of a solution of the so-called black ash are now commercially marked for caustic alkali. These liquors contain the following compounds :—

1. Chiefly hydrate of soda.
2. Some quantity of carbonate of soda.
3. Several sulphur compounds of sodium,—viz., sulphide of sodium, hyposulphite of soda, sulphite of soda, and sulphate of soda.
4. Sulphide of iron held in solution by the sulphide of sodium.
5. Chloride of sodium.
6. Several cyanogen compounds of sodium, and especially ferrocyanide of sodium.

These liquors are evaporated in large cast-iron pots, and in order to destroy or oxidise the sulphides of sodium and iron, as also the cyanogen compounds, an equivalent quantity of soda-saltpetre is added. All the oxidable sulphur compounds, together with the small quantity of sulphide of iron, are changed to sulphate of soda and peroxide of iron by the nitrate of soda in the boiling liquid at a temperature not below 260° to 270° F. The cyanogen compounds, on the other hand, are not decomposed by the nitre until the liquor begins to pass from the watery into the dry fusion, and the uncombined water of the hydrate of soda has been driven off. When the whole mass of alkali (generally about four tons) reaches a low red heat, a regular evolution of gas is observed : this is evidently owing to the oxygen produced by the decomposition of the nitrate and to the nitrogen from the decomposition of the cyanides; at the same time, a plentiful liberation of graphite is observed, covering the whole surface of the liquor with a bright layer of graphite. This liberation of graphite is still more plainly seen if no nitre be added to the liquor at first, or only so much as is sufficient to oxidise the sulphur compounds; but if a few pounds of nitrate of soda be added when the water has been driven off, and the mass is allowed to become red-hot, a violent reaction takes place, and a large quantity of graphite is set free. This sudden liberation of graphite proves that this substance cannot be derived from the cast iron of the pot in which the fusion is made. So violent is the evolution of gas that a complete cloud of fine particles of caustic soda is carried up into the air, rendering it almost impossible to remain in the neighbourhood of the operation. In this way all the cyanogen compounds are completely decomposed, the iron in the ferrocyanide of sodium becomes peroxide, and in a few hours falls to the bottom of the pot. If the right quantity of saltpetre has been added, a colourless mass of fused caustic soda remains; but if too large an amount of nitre has been added the liquor becomes coloured deep green, owing to the formation of manganate of soda. It is remarkable that, in the absence of nitrate of soda, the cyanogen compounds act reducingly upon the sulphide of sodium. This is seen from the fact that a portion of the soda-lye, which gives no sulphide reaction with a lead salt, produces a blackening after the caustic alkali has been heated to redness.

The graphite may be skimmed off the surface of the fused alkali, and when washed with water and hydrochloric acid it appears in the form of an extremely fine, bright powder. If allowed to swim on the top of the almost red-hot fused soda, the graphite is oxidised gradually, and, after the lapse of about three or four

hours, it altogether disappears. Heated in a platinum crucible by itself, it is incombustible; but it generally contains small particles of charcoal mixed with it, and these undergo oxidation.

The temperature at which this evolution of graphite takes place is a very low one compared with that at which graphite is liberated from cast iron; for a thin iron wire can scarcely be brought to a visible red heat by dipping it into the fused alkali.

From this peculiar decomposition, it would appear that we have good reason to assume that the carbon contained in cyanogen is present in the graphite modification; for if this be not the case, how is it that the easily-combustible charcoal can withstand the oxidising action of the saltpetre, whilst none of the iron of the ferrocyanide of sodium has been reduced to the metallic state?

It has, besides, been lately shown by M. Caron that the formation of steel—i. e., the combination of iron with carbon in the graphite modification—can only take place in presence of cyanogen compounds, and that no carbon whatever is taken up by the iron when this metal is heated with other carboniferous gases. The mode of production of graphite noticed in this communication appears to be an intermediate reaction between that from the carbide of iron and from the nitride of carbon.

As in the process of cementation, it is seen that the carbon of the cyanogen is taken up by the iron without being set free; so this reaction proves that cyanogen can be split up into its constituent parts without either of them combining with a third body.

Despretz asserts that the carbonisation of iron is always preceded by a combination of this metal with nitrogen,—a process which makes it porous and more fit for uniting with carbon. The correctness of this supposition has, however, become rather doubtful by Caron's recently-published experiments (*Comptes-Rendus*, 1860).

To conclude, I beg to say some words about the formation of native graphite. I do not think that this body has been formed from coal or diamond, but I rather believe it has been separated out of carbon compounds as graphite by processes perhaps analogous to those above described.—*Proc. Manchester Phil. Soc.*

On White Lead, by WILLIAM BAKER, F.C.S.

THE following observations on the composition of white lead, in addition to those published in a recent Number, may not be uninteresting to your readers. My analyses refer to Dutch white lead, or carbonate of lead containing some hydrate of lead produced by means of acetic acid and spent tan, and it will be seen that no fixed and definite formula can be written for the commercial dry white lead. It is rather a carbonate, containing a variable proportion of hydrate, that depends upon the conditions under which the corrosions are produced. Thus, in a single bed of corroded lead a number of samples may be selected all varying in the proportion of carbonate to hydrate. Near the side walls, where the aqueous vapour, loaded with carbonic acid, freely ascends, it will be found that, under some circumstances, corrosions of a sugary character are produced, which, upon examination, are found to be a mass of minute transparent crystals of neutral carbonate of lead. Again, on the surface of the corrosion, a thin, scaly layer sometimes separates, which is also near in composition to the neutral carbonate. The quantity and quality of the water employed in grinding

and washing the corrosions to a pulp, doubtless influences the ultimate composition of the dry white lead, especially as the water usually contains free acetic acid and acetate of lead obtained from the corrosions. In proof of this, I submit the following analyses of dry white lead from different manufactories, which agree very well with those published by Professor Mulder:—

	No. I.	Calculated.	Equivalent.
CO ₂	11.03	11.4	= 2
HO	2.23	2.3	= 1
PbO	86.11	86.3	= 3
	No. II.	Calculated.	Equivalent.
CO ₂	12.17	12.7	= 3
HO	1.66	1.7	= 1
PbO	85.37	85.6	= 4
	No. III.	No. IV.	Calculated. Equivalent.
CO ₂	13.37	13.48	13.4 = 4
HO	1.11	1.46	1.4 = 1
PbO	84.71	84.88	85.2 = 5

The hygroscopic water is generally not more than 0.50 per cent.

No. 1, London white lead; No. 2, Newcastle ditto; Nos. 3 and 4, Sheffield ditto.

I do not mean to assert that the product of these manufactories is always of the same composition; for I have made analyses of the Sheffield white lead in which the oxide of lead comes up to 86 per cent. The other constituents were not estimated; but this is sufficient to show that it was then near the composition of the London sample, No. 1. This variation in the manufactured white lead will be still better understood on consideration of the following analyses of corrosions. These have been selected to show the variability of their composition, although Nos. I. and II. may be considered of the normal kind.

No.	CO ₂ .	HO.	PbO.
1. Good solid corrosion	12.49	1.60	85.24
2. " " "	12.31	1.72	85.77
3. Shelly surface of corrosions	15.14	0.53	83.86
4. Hard, flaky corrosion	15.14	0.60	84.10
5. Colourless, crystalline, and transparent corrosions	15.71	0.75	83.53
6. Colourless, transparent crystals, picked out from a mass of sugary corrosion	16.11	0.49	83.39
7. Calculated neutral carbonate	16.50	—	83.50

It will be seen that Nos. 5 and 6 are evidently the neutral carbonate containing only a trace of hydrate. Nos. 3 and 4 illustrate the passage from the latter to the normal corrosion, which may be represented, if a formula is desired, by $\text{PbOHO} + 3\text{PbOCO}_2$.

Lead Works, Sheffield.

On Ozonised Hydrogen and Oxygen, by M. H. OSANN.¹

THE hypothesis having been published, that the author's ozonised hydrogen might derive its more energetic reducing power from the production of one of the inferior acids of sulphur accompanying the hydrogen disengaged from the voltaic battery, M. Osann endeavoured to find whether this explanation was tenable. After passing a current of ozonised hydrogen during an hour through a certain quantity of water, he found that the water remained neutral, which would not be the case supposing the gas were mingled with an acid of sulphur.

¹ *Journal für Praktische Chemie*, vol. XXXI., p. 20, 1860, No. 17.

He then wished to take account of the relative quantities of ozonised hydrogen absorbed by a solution of silver, and of the reduced silver. Electrolytic hydrogen, twice washed in distilled water, was left for some time over a solution of nitrate of silver. The gas was measured before and after absorption, and the tension of the water vapour estimated, and the reduced silver weighed. This silver did not contain the slightest trace of sulphur, which is also in contradiction to the hypothesis in question. It has been found that on an average 100 cubic centimetres of absorbed gas precipitate 1.43 grammes of metallic silver. (The results varied from 1.14 grammes to 1.80 grammes.) The proportion of absorbed gas being 1.42 to 3.52 per cent. of the volume employed. Regarding 1.43 grammes of silver as equivalent to 100 cubic centimetres,—that is to say, to 0.0038 grammes of ozonised hydrogen, 0.66 will be found the equivalent of ozonised hydrogen, or $\frac{2}{3}$ ds of the equivalent of ordinary hydrogen.

These results led M. Osann to revert to an opinion he had abandoned after Mr. Andrews' experiments, and to admit that ozone and ordinary hydrogen have different equivalents.

M. Osann thought he could establish the equivalent of ozone by analysing the yellow body produced when ozonised oxygen is passed through a solution of oxide of lead in caustic soda, or when the same solution is decomposed by the electric pile. According to the author, this body is characterised as a combination of ozone by the property it has of turning blue the alcoholic tincture of guaiacum. The most simple hypothesis possible touching this body is, that it is composed of oxide of lead and ozone ($Pb\ O, Oz$).

There has been found in the yellow body obtained by ozonised oxygen,—

Lead, 89.52. Oxygen, 10.47.

Giving 4.27 as the equivalent of ozone. The yellow body obtained by the electric pile contained,—

Lead, 88.86. Oxygen, 11.14,

from which 5.16 may be deduced as the equivalent of ozone.

From these two experiments, the author concludes that the mean is 4.71, which he finds agrees very nearly with the results formerly obtained in his numerical determinations on ozonised hydrogen and ozone.

We have reported, with some detail, M. Osann's experiments, though it is impossible for us to admit his interpretation of them. His first analysis would lead to the formula Pb_2O_3 , which requires $Pb\ 89.6, O\ 10.4$. It results from this, that the yellow substance analysed appears to be a kind of minium, having PbO_2, PbO for its formula.

Besides, it is evident that if ozone were an allotropic modification of oxygen, its atomic weight would be that of oxygen or of one of its multiples.

Analytical Notes.

Estimation of Nitric Acid.—Fresenius dissolved a known weight of fine piano-wire in an excess of muriatic acid, contained in a retort through which hydrogen passes; the nitrate is afterwards thrown in, and, after the dark colour has disappeared, the amount of protoxide in the cooled solution is determined by permanganate of potassa. The quantity of peroxide is now easily calculated, and from it the amount of nitric acid by which it

had been peroxidised.—*Ann. d. Chem. und Pharm.*, xxx. 217—219.

Estimation of Silver in the Metallic State.—Fellenberg proposes to dissolve the chloride of silver in ammonia, dilute with water, precipitate by a strip of bright copper, collect and wash the silver upon a filter, incinerate and fuse with borax; or to incinerate the filter containing the chloride, without fusing the latter, and reduce it by means of pure lead upon bone ashes. These processes avoid the tedious drying of the filter and the precipitates.—*Schweiz. Zeitschrift*, v. 121—122.

Estimation of Arsenic.—A solution of pentasulphide of arsenic (As_2S_5) in sulphide of ammonium yields instantly a precipitate of ammonio-arsenate of magnesia by a solution of magnesia. Lenssen states that the sulphides of tin and of antimony are not precipitated under the same conditions.—*Ann. d. Chem. und Ph.*—*Wittst. V. Schrift*, ix. 574.

Separation of Phosphoric Acid from Sesquioxide of Iron and Alumina.—W. Mayer states that the requisite proportions to effect this separation are, for 1000 cubic centimetres 15 grammes (1 equivalent) tartaric acid, 6 grammes (1 equivalent) anhydrous sulphate of magnesia, and 16.5 grammes (3 equivalents) of chloride of ammonium. With other proportions ammonia produces a precipitate containing besides ammoniophosphate of magnesia, also basic tartrate of magnesia.—*Ann. d. Ch. und Pharm.* xxv.

Phosphomolybdate of Ammonia.—E. Spiess, of Munich, and Professor V. Eggertz, of Fahlun, corroborate Nuntzinger's analysis of this compound, who calculated, after drying at $212^\circ F$, the following formula:— $4(H_2NO, 10MoO_3) + (H_2NO + [8MoO_3, 2PO_3]) = 3.577 NH_4O, 3.962 PO_3, 46.1 MoO_3$.—*Wittst. V. Schrift*, ix. 527—429.

Anhydrous Oxalic Acid = C_2HO_4 is, according to Erdmann, obtained at ordinary temperature over sulphuric acid; it is proposed by him for preparing the normal acid of volumetric analysis.—*Journ. f. prakt. Chem.* lxxv. 4, 5.

Silicon in Iron.—The black residue left after dissolving crude iron in muriatic acid was found by Schafhäütl to evolve hydrogen from ammonia. Wöhler has proved it to contain oxide of silicon.—*Ann. d. Chem. und Ph.*, xxviii. 374.

Reaction of Strychnia.—The solid strychnia when mixed with solid iodic acid or iodate of potassa and a drop of strong sulphuric acid assumes, according to X. Landerer, on the application of a gentle heat, a beautiful violet colour, gradually changing to red-brown, remaining unchanged for many days. The thick liquid shows, after a few hours, a beautiful iridescence, continuing for several days.—*Hirzel's Zeitschrift*, xii. 86.

Protochloride of Iron is obtained pure, according to E. Amaler, by evaporating the recent solution almost to dryness, and adding powdered iron and strong muriatic acid in the proportion of one part of the former to five of the latter; the mixture is then evaporated to dryness with continued stirring by an iron spatula. The nascent hydrogen evolved will effectually reduce all the sesquioxide of the protochloride and the dry salt will keep for a considerable time.

Tin in Vinegar.—Investigations caused by the State authorities in Potsdam have developed the fact that pure vinegar carried in bright tin measures from the cellar to the store contained a small quantity of tin, which increased on standing, and was considerable after boiling. Tin measures may probably be frequently the cause of

the deleterious effects of vinegar, looked for in other circumstances.—*Arch. d. Med. Ges.—Arch. d. Pharm.*, cli. 115.

TECHNICAL CHEMISTRY.

Report on the Sanitary Condition of the City of London, for the Quarter ending June 22, 1861, with Table of the Composition of the River, and the Water from City Pumps, by H. LETHEBY, M.B., M.A., Ph.D., Medical Officer of Health for the City of London, &c., &c.

Meteorology and Condition of the River.—The mean temperature of the season has been about one degree below the average of former years (51.4°), and the thermometer has ranged from 82° to 36° . The daily range, however, has sometimes been as high as 24° . This, conjoined with the humidity of the atmosphere, which has averaged 85 per cent. of saturation, has been the cause of the large increase of lung diseases.

In the Spring Quarters of 1858 and 1859, when the river was so offensive, the average humidity of the air was only 68 and 69, and the mean temperature was 57.6° and 59.8° . During those quarters the warmth of the river, and the evaporation from its surface were considerable: indeed in the month of June of 1858 the temperature of the water was 72.4° , and in the corresponding month of 1859 it was 67.2° . In the succeeding months it rapidly rose to the temperature of 75° , and then the putrefaction of the water was at its highest; but during the quarter which has just expired, as well as that of 1860, the temperature of the river has not exceeded 62° , and there have been but slight signs of putrefaction. The conditions, therefore, which seem to be necessary for a high state of decomposition in the river are, a continued absence of rain, a hot spring, and a dry condition of the atmosphere. The temperature of the water must be over 60° , the rainfall less than 2 inches in the month, and the humidity of the air below 80° . With these conditions there is not only a diminished supply of fresh water from the upper tributaries of the river, but the volume of the stream is still further diminished by rapid evaporation from its surface. Under these circumstances the daily supply of sewage becomes concentrated, the downflow of the current arrested, and oceanic water rises in the bed of the river to maintain its tidal level. Then it is that the mixture of sewage and sea-water putrefies and becomes a nuisance. This state of things may be predicated not only by the temperature and dryness of the air, but also by the chemical composition of the water; for when the proportion of saline matter, at high tide at London Bridge, amounts to more than 60 grains per gallon, there is imminent danger of the river becoming offensive. This is the result of almost weekly observations made over a period of four years. As far as I know, there have not been any similar consecutive examinations made, and therefore they may be of service when the question arises as to the influence of the new system of drainage on the state of the river. Last year, and up to the present month of this year, the river has been in a normal condition; for its composition has not been very different from that recorded in the early analyses of Dr. Lambe and Dr. Bostock. In the course of the whole year, the proportion of saline matter dissolved in the river-water at high tide at London Bridge has amounted to only 28.9 grains per gallon, and the organic

matter to 3.3 grains. The range has been from 19.6 to 57.3 , and the organic matter from 2.6 to 5.5 . The chief constituents of the saline matter have been as follows:—carbonate of lime 12 grains, sulphate of lime 4.5 grains, common salt 10 grains, alkaline nitrates about 2 grains, and ammonia in combination 1.3 grains. The quantity of suspended matter in the water has averaged only 6.4 grains to the gallon. At times it has risen to from 12 to 15 grains, but this has happened during high winds, as at the time of the equinoxes, when the surface of the water has been ruffled, and the mud upon the shore disturbed. The principal constituent of the suspended matter is ferruginous clay, and with this there is combined about one-fifth of its weight of organic impurity. It is remarkable that the river water near to the shore is always a little less impure than at mid-stream. This arises from the influx of fresh water, and perhaps also from the purifying influence of the atmosphere on the thinner stratum of liquid; as well as from the circumstance that the main current of the rising tide is in the middle of the stream.

The Water Supply and City Pumps.—In the course of the quarter, I have examined the water supplied to the City by the New River Company, and I have also analysed the water furnished by 22 of the City pumps. The first-mentioned supply has not been objectionable; for the quantity of saline matter dissolved in the water has amounted to only 17.4 grains per gallon, and the organic matter to less than 2 grains (1.9). The chief constituents have been as follows:—Carbonate of lime, 12.6 grains per gallon; sulphate of lime, 1.9; alkaline sulphate, 0.2; alkaline chloride, 1.2; alkaline nitrate, 1.0; silica and alumina, 0.5; and organic matter with traces of ammonia, 1.9. These results do not differ very materially from those obtained by Dr. Dundas Thomson, and reported in the Weekly Returns of the Registrar-General; and they show that the water is of good quality and is well suited for domestic purposes. Another advantageous property of the water is, that it is entirely without action on lead, and may, therefore, be stored in lead vessels, and distributed by lead pipes, without danger to the public health.

The quality of the water supplied by the City pumps is very different from that of the New River, for instead of an average of only 19 grains of solid matter per gallon, the water contains from 20 to 127 grains. Taking the pumps in the order of their foulness, they stand as follows:—Bishopsgate Street Without, 127.3 grains per gallon; Aldgate pump, 109.5; Cock and Hoop Yard, Houndsditch, 89.2; Bishopsgate Street Within, 89; Bride Lane, 84.7; Bow Church Yard, 84.5; Fenchurch Street, 83.1; Little Britain, 83; Basinghall Street, 81.6; Chequer Yard, Dowgate Hill, 81.1; Bell Yard, Gracechurch Street, 80; Idol Lane, 78.5; Ironmonger Lane, 76.2; Bartholomew Lane, 75.3; Cornhill, 74.8; Bowling Square, White Lion Street, 71; Half-moon Passage, 70.5; Great St. Helen's, 53.3; Gutter Lane, 45.7; Honey Lane Market, 44.2; Guildhall Buildings, 28; and Glovers' Hall Court, 19.8. The quantity of organic matter in them ranges from 1.5 grains per gallon to 8.8; the common salt from 2.7 to 25; the sulphate of lime, from 2 to 29; the alkaline nitrates, from 2.1 to 24.6; and the combined ammonia from 0.5 to 2 grains per gallon. These results show that the City pumps are not only charged with decaying organic matter, but also with the saline products of its oxidation; the ammonia, for instance, is a sign of present putrefaction, and the alkaline nitrates of a past; besides which, the existence of so large a quantity of common

salt is suggestive of the filthiest impurities, as, for example, the fluid matters discharged from the human body, and the percolations from cesspools and sewers. Most of these waters are bright and sparkling, and they have a cool and agreeable taste. They are, therefore, much sought after for drinking purposes; but the coolness of the beverage and the briskness of its appearance are dangerous fascinations, for they are both derived from organic decay. Dead and decomposing matters have accumulated in the soil, and have been partially changed by its wonderful power of oxidation, and thus converted into carbonic acid and nitre. These have given to the water the agreeable qualities which are so deceptive. In reality, the water from the City pumps is far worse than that from the muddy river, from which it is in great part derived; indeed, it may, at any moment, become charged with the active agents of disease; for no one can say when the salutary influence of the soil may fail, by being worn out or over-taxed, and then the putrid organic compounds will pass into the wells unchanged. Many of the pumps are in close proximity to the fat graveyards of the City, and it is more than probable that all of them derive a portion of their water from these sources, for they are the principal gathering grounds for the surface springs; in fact, they are the only open spaces through which the rain can percolate to reach the shallow wells. Hereafter, when I have completed the inquiry into all the City pumps, I shall discuss this matter more fully; now, however, I merely direct attention to the general foulness of the water, and to the danger which may arise from the use of it. In the following Table I have shown the composition of those wells which have already been examined:—

Table of the Mean Composition of the New River Water as supplied to the City, during the Spring Quarter of 1861; of the Thames at High Tide; and of the Water from some of the City Pumps.

Source of the Water.	Constituents per Imperial Gallon.										Total.
	Carbonate of Lime and Magnesia.	Sulphate of Lime.	Alkaline Sulphate.	Alkaline Chloride.	Alkaline Nitrate.	Silica.	Alumina, &c.	Organic Matter.

In every case the Water from the City Pumps was clear, and of a slight greenish tinge. It was exceedingly hard, and was without action on lead.

Sanitary Work.—The proceedings have had the effect of checking the supply of bad meat to the markets, for the total amount seized during the quarter is not half so much as that of the preceding quarter, and during the last month the quantity has fallen off very considerably.

Arrangements have been entered into with Mr. Ford, of Bell Isle, for the destruction of the meat thus seized; and to ensure its not being used as food, a chemical treatment is about to be adopted, before the meat leaves the custody of the Inspectors.

The last point to which I have to refer is the working of the Act for preventing the sale of adulterated food. Only six applications have been made to me during the quarter for the analysis of articles suspected to be adulterated; two of these were for beer, one for bread, one for milk, and one for cooked ham. Both of the samples of beer were of inferior quality, and one was adulterated with a sweet material, like liquorice; the bread also was of inferior flour, but the other things were sound.

On the Origin and Progress of the Phosphorus and Match Manufactures, by G. GORE.

(Continued from page 47.)

THE following is the general process of manufacture of matches as now in use:—The wooden splints for the matches are prepared from the very best quality of pine planks, perfectly desiccated at a temperature of 400° Faht. Each plank is cut into about thirty blocks about eleven inches long, four and a-half inches wide, and three inches thick. A block is fixed with its small end downwards between two uprights, the grain of the wood being horizontal. A frame, having fixed upon its upper surface about thirty lancets one-eighth of an inch asunder, with their points projecting upwards one-eighth of an inch, reciprocates to and fro beneath the end of the block of wood by means of a crank, and in doing so scores the whole of the lower surface of the block with a number of parallel cuts, about one-eighth of an inch apart and one-eighth of an inch deep, in the direction of its fibres. Immediately upon this a sharp blade, or scythe, swings round horizontally beneath, and cuts off the scored surface to the thickness of one-eighth of an inch, in the form of square splints four and a-half inches long, which fall through a shoot into a room beneath. The block now sinks one-eighth of an inch and the operation is repeated. In this way between two and three millions of splints are readily formed by steam power in a single day. English splints are of two sizes—large and minikins: the larger ones are two and a-quarter inches long (or double-length, as first formed, i.e. four and a-half inches), and the minikins are rather shorter.

In England the splints are square in form, and produced as above; but in Germany they are cylindrical, and are prepared in this shape by placing the small block of wood with the ends of its fibres downwards upon a strong plate of steel of larger surface, perforated over the greater part of its surface with holes of the size of the splint, countersunk at their entrances to form cutting edges, and as close together as possible. Great pressure being now applied to the upper end of the block, it is forced through all the holes, and reappears on the lower side of the steel plate in the form of a heap of cylindrical splints.

Returning to the English splints—they are collected

as they are cut, and measured into bundles of six dozen each by a man who seizes a number of them in his hands from the loose and irregular heap, and by dexterous jerking, knocking, and shaking, arranges them parallel to each other, then places them in a short open gutter or cradle, across which he has previously thrown a piece of string, and when the measure is full to the level of its edges he ties up the bundle, throws it aside, and proceeds with another with equal rapidity. The bundles are then perfectly dried by exposure for several hours in a heated oven.

The bundles of splints are next coated at both ends with sulphur. A quantity of brimstone is melted in an iron pot, and one end of a bundle being quite scorched by contact with a red-hot plate is immersed into the melted sulphur to the requisite depth; then repeatedly swung in the air, to throw off the superfluous sulphur, and rolled violently upon its axis and beaten, to prevent the splints adhering together in one mass as the sulphur hardens. The other end is then similarly treated. In some cases the ends of the splints are saturated with wax instead of sulphur in a similar manner.

A child now arranges the splints in a number of successive rows, one above another, in a frame, each splint separate from the others, in the following manner:—He takes a narrow wooden frame composed of three fixed pieces, a narrow bottom cross-piece about sixteen inches long and two inches wide, with two vertical pegs about eight inches high, one at each end; and has by his side about two dozen loose strips of wood of similar length and width to the bottom piece, and with holes or notches at their ends to receive the upright pegs; each of these strips has a series of fifty transverse shallow notches upon its upper surface to receive fifty splints, and is covered on its lower side with felt or other soft material. Having placed one of these strips upon the bottom piece, he takes up a handful of splints and quickly deposits fifty of them, one in each groove, their ends projecting one and a-quarter inches on each side; he then places another strip upon the first one, and fills it in like manner, and so on until the pile of twenty-four rows is complete. A thicker strip of wood, similar to the bottom piece, covered upon its lower side with felt, is then placed upon the top, and the whole secured moderately tight by means of thumb-screws, or pegs fitting into holes in the uprights. The splints are then ready for being tipped at their ends with the phosphorus composition. Many children are employed at this kind of labour.

The exact ingredients, and their proportions, in the phosphorus composition, differ in different countries and with different manufacturers, but they all consist essentially of emulsions or mixtures of phosphorus in a solution of glue or gum arabic, with or without other matters for increasing the combustibility, for colouring, &c. In England the composition contains a considerable quantity of chlorate of potash, which imparts a snapping quality, and noisy projecting flames, and but little phosphorus, on account of the moisture of the climate; other substances are also added to give hardness and power of resisting moisture. The following is about the composition of the best quality:—

Water . . .	4	parts by weight.
Glue . . .	2	"
Phosphorus . .	1½ to 2	"
Chlorate of potash .	4 to 5	"
Powdered glass .	3 to 4	"

In Germany the proportion of phosphorus used is much larger, and gum is used instead of glue, together with

nitrate or peroxide of lead, and no chlorate of potash. In consequence of the presence of so much phosphorus and the absence of chlorate of potash, the German matches light quietly, with a mild, lambent flame, and are injured quickly in a damp place by the oxidation of the phosphorus and the production of phosphoric acid, which attracts moisture. One of their mixtures, given by Böttger, is composed as follows:—

Phosphorus . .	4	parts by weight.
Nitrate of potash .	10	"
Fine glue . . .	6	"
Red ochre . . .	5	"
Smalt	2	"

In every case the glue is first broken into small pieces and soaked in cold water until quite soft, then added to the requisite quantity of water and heat applied by means of a water-bath until it is quite fluid, and at a temperature of 200° to 212° F. The vessel is then removed from the fire, the phosphorus gradually added, and the mixture agitated briskly and continually with a stirrer, having wooden pegs or bristles projecting at its lower end. The chlorate of potash, colouring, and other matters, all in a state of very fine powder, are then added, one at a time, to prevent risk of accident, and the stirring continued until the mixture is comparatively cool. By this means the minute particles of phosphorus are kept from uniting into large globules, and the heavier matters are prevented from sinking to the bottom.

In the process of tipping the ends of the matches (termed in the manufactory "dipping"), a quantity of the composition is spread, by means of a large palette-knife, upon the horizontal surface of a smooth stone or plate of iron, heated by means of steam beneath. The mixture becomes much more fluid by the heat, and is spread to a width and length of about ten inches by twenty, and a uniform depth of about one-eighth of an inch by means of a horizontal gauge. The "dipper" then takes a frame filled with splints, as already described, strikes the ends of the splints upon a bare part of the stone until the whole of those ends exhibit a flat, uniform surface. He then dips those ends, either once, twice, or more times, into the mixture, until they have all received a proper amount, and hands the frame to a boy, who places it upon a rack in a current of air, in order that the composition may cool and harden. Meanwhile the dipper proceeds with other frames in like manner, and replenishes the layer of composition occasionally. After a number of frames have been thus dipped, and the composition upon the splints in them has partly hardened, they are all taken, one by one, in the original order, and the other ends of the splints tipped in a similar manner. With six dipping-stones, half-a-dozen workmen have dipped as many as twenty millions of matches in a single day. This method of dipping is termed "frame-dip"; but there is another process called "bundle-dip," which consists in taking a bundle of the sulphured splints, twisting it in such a manner that the ends of the splints spread out like a brush and separate from each other; they are then tipped with composition like the others. In this process the *ends* only of the splints acquire a coating of the mixture, whereas in frame dipping the composition extends a short distance up the *sides* of the splints and is more firmly attached. Bundle-dipped matches are inferior to frame-dipped ones.

In the manufacture as now being described it will be observed that each splint is 4½ inches long, coated with composition at both ends, and will therefore form two

matches by being cut asunder in the middle; but this is not always the mode of proceeding; in some manufactories the splints are cut in two before being dipped, and are tipped at one end only.

As soon as the composition is partly dry, and of such a degree of hardness as to bear the next operation without igniting and without rubbing off, the splints (those coated at both ends) are quickly removed from the frames into parallel heaps, and the frames set at liberty. A man now takes a heap of fifty of the splints, places them between two vertical supports in a horizontal channel or trough of wood, passes a string with a weight over them to prevent their falling about, and cuts them through at their middle by means of a cork-cutter's knife, moving upon a hinge like a chaff-cutter's scythe. He then places them in heaps of 100 matches each, ready for boxing. The little boxes are now filled by women and children, who perform the operation with exceeding rapidity, and before the matches are dry, in order to avoid accidents. Each match passes through the hands of about seventeen persons, chiefly children, in its process of manufacture.

Trays of sawdust are placed near the various workmen and operators to plunge the matches into in case they ignite. Vessels of water are also freely at hand in case of accident. Also a quantity of sand is strewed in a layer of several inches deep beneath the racks upon which the frames of matches are set to harden, so that in case of a frame of matches falling, the flames may be quickly extinguished. A lotion, composed of olive oil and lime water, is exceedingly useful to apply to the skin in cases of burning by phosphorus.

(To be continued.)

Working in Aluminum.

WE extract the following valuable article from the *Ironmonger*. The information is obtained from Messrs. Bell and Brothers, Newcastle-on-Tyne, manufacturers of aluminum.

The peculiar properties of this substance having been so little understood, has hitherto hindered its general employment, but now that it is sold in a pure state at as low a rate as 50s. per pound avoirdupois, it is likely to be much more frequently used.

Aluminum is a metal of fine white colour, slightly inclining to blue, especially after being well hammered when cold.

Aluminum, like silver, is susceptible of a very fine "matting," which is not affected by exposure to the air, or by any of the impurities usually present in the atmosphere of towns. To obtain this matting, the aluminum objects (being previously washed in benzole or essence of turpentine) must be plunged into a weak solution of caustic soda, thoroughly well washed, and exposed to the action of strong nitric acid. When the desired matting has been obtained, it must be well washed again, and dried in sawdust.

Aluminum is easily polished or burnished. To do this, it is necessary to use a mixture of equal parts of rum and olive oil, as an intermediate substance between it and the polishing stone or powder used. The polishing stone is steeped in this mixture, and will then burnish aluminum in the same manner as gold and silver is burnished, care being taken not to press too heavily upon the burnishing instrument.

Aluminum can be beaten out, either hot or cold, to the same extent and as perfectly as gold or silver; and

it is susceptible of being rolled in much the same way as either of the above metals. Leaves as thin as those used for gilding and silvering can be made of aluminum. Covered ingot moulds of iron answer best for receiving aluminum intended to be used in the rolling mill. Aluminum quickly loses its temper, and therefore requires frequent reheating. The temperature of this reheating is a dull red heat, and when the plates become very thin, this demands the greatest attention.

Aluminum is easily drawn into wire. For this, the ingots are run into an open mould, so as to form a kind of quadrangular shape of a little less than half-an-inch section, which is then beaten upon the edges by the hammer very regularly; the operation of drawing out is then commenced on a horizontal bench, by very gradually reducing the diameter of the metal intended to be drawn into wire, and by frequent reheating, and then the ordinary process of wire-drawing can be proceeded with. When the threads are required extremely fine—as, for example, for the manufacture of lace—the heating becomes a very delicate operation, on account of the fineness of the threads and the fusibility of the metal. The heat of the current of air issuing from the top of the glass chimney of an Argand lamp will suffice for the heating.

The elasticity of aluminum is very much the same as that of silver, and its tenacity also about the same. The moment after it has been melted aluminum possesses about the hardness of pure silver; when it is hammered out, it almost resembles that of soft iron; it becomes elastic, acquiring, at the same time, considerable rigidity, and emits the sound of steel when suffered to fall on a hard body.

A property which aluminum manifests in a high degree is that of excessive sonorousness. This property has already rendered it of service in the construction of several musical instruments.

Aluminum is much lighter than ordinary metals. Its density is 2.56, a quarter that of silver, and about a third that of iron. By the action of the hammer, the density of aluminum increases sensibly, so as to become equal to 2.67.

Aluminum melts at a higher temperature than zinc, and a lower one than silver; to melt it, an ordinary earthenware crucible must be employed, without the addition of any sort of flux.

Its low point of fusion, along with its slowness of heating, require that for melting it a less intense fire should be used, but applied for a longer time than in melting silver.

It is easily melted in an open crucible, which facilitates the removal of the dust and other impurities which appear on the surface of the metal; and for the purpose of stirring the entire mass, a clean iron spatula is used.

Aluminum is easily run into metallic moulds; and, still better, for objects of a complicated form, into moulds of dry porous sand, formed so as to allow an easy passage for the air expelled by the metal, which is viscous when melted. It ought to contain a greater number of passage holes, and should be so managed as to run it in one long and perfectly cylindrical gut. When heated to a red heat, it ought to be poured out with tolerable rapidity. A small portion of the fused metal should be caused to run into the gut itself when full, to compensate for the contraction of the substance of the metal at the moment of solidification.

By following all these precautions, castings of the highest degree of fineness may be obtained; but, at the

same time, to succeed perfectly, an especial acquaintance with the subject is needed.

In the production of work where the use of the lathe becomes necessary, any scratching or tearing of the metal by the tool is avoided by covering the surface to which the tool is applied with a varnish composed of stearic acid and essence of turpentine.

When aluminum is soiled by greasy matters, it can be cleaned by benzole; if it be soiled by dust only, india-rubber, or very weak soap and water may be used.

The pieces of aluminum intended to be soldered must be prepared in the same manner as objects are treated for soldering with tin, viz., by a "tinning;" but it must be remembered that it is indispensable that this tinning must take place with the solder itself. The pieces to be soldered, thus tinned beforehand, are afterwards joined together, and exposed to the flame either of a gas blowpipe, or any of the ordinary sources of heat used in such cases. In order to unite the solderings, small tools of aluminum are used. These tools are used as little soldering instruments, and they facilitate at the same time the fusion of the solder, and its adhesion to the previously prepared aluminum.

The use of tools of copper or brass used when soldering gold and silver, must be strictly avoided, as they would form coloured alloys with the aluminum and the solder. It is of the greatest importance never to use any flux to cause the solder to melt, as all those at present known attack aluminum, and prevent the adhesion of the pieces to be soldered. The use of the little tools of aluminum is an art which the workmen must acquire by practice; in fact, at the moment of fusion the solderings must have the friction applied, as they melt suddenly in a complete manner. In soldering aluminum, it is well to have both hands free, and to use only the foot for the blowing apparatus.

Solders of different compositions and degrees of fusibility have been employed in soldering aluminum. The following are those which have been generally used, ranged according to their order of fusibility:—

	I.	II.	III.	IV.	V.
Zinc . . .	80	85	88	90	94
Copper . . .	8	6	5	4	2
Aluminum . .	12	9	7	6	4

No. 4 is the one usually preferred, particularly for soldering smaller objects.

In order to make the solder, the copper is first melted, the necessary aluminum is added, and stirred by means of an iron spatula, unpolished, as it comes from the blacksmith, adding also a little tallow; the zinc is then added, avoiding too much heat, as this last metal is easily oxidized, and is very volatile.

NOTICES OF BOOKS.

Water: its Impurities and Purification. By F. HAHN DANCHELL. London: H. Renshaw, 356, Strand, W.C.

UNDER the above title a little work has been published which will be found of considerable use to those of our readers who, without going to the expense or trouble of obtaining a complete qualitative or quantitative analysis of a water, may still desire to know by a few simple tests what injurious substances are likely to be present, and how they are to be got rid of. The work is intended to accompany a simple water-testing apparatus, which consists of a selection of tubes and bottles of various appropriate tests of definite strength, so that by adding to

successive tubes full of water a certain number of drops of each test in rotation, the presence or absence of ammonia, decomposed organic matter, lead, carbonate of lime, sulphate of lime, sulphuric acid, and iron, may be ascertained. The author states in his preface:—"To the head of every family it presents a ready means of ascertaining the purity of that substance which is the most extensively used, and the most absolutely essential of all those required for the support of our existence; to the keeper of horses and cattle it will, I believe, point out many of the hitherto concealed sources of the mysterious epidemics and diseases from which such severe losses have arisen; the agriculturist, by its means, will be enabled to determine the probable advantages to be derived from the use of any particular water for irrigation; the manufacturer may ascertain the nature and suitableness of the water supplied for his use; whilst to emigrants, about to choose their future home, it will have an especial value, as indicating the localities which, if health be valued, are to be chosen or avoided. And although my little apparatus has no pretensions to supply the place of, or dispense with the necessity for, an accurate qualitative and quantitative chemical analysis, I yet venture to think it will be found of use by medical and scientific men, who may have occasion to ascertain, in a ready way, whether any of the more usual impurities are present or not in water. The tests being all made dependent upon colour, and the mode of operating being merely the addition of a few drops of the test fluids to water, no chemical knowledge is required for their application. The tests are all sufficiently delicate and accurate for practical purposes, and the apparatus is extremely portable, and conveniently arranged. I have by means of these tests placed it in the power of the public to ascertain for themselves whether the representations made by myself and other filter makers are well founded or not. By means of these tests, not only can the condition of the natural water be ascertained, but the state of purity in which it is left after passing through the filtering medium may be ascertained with just as great certainty and ease."

The importance of a plentiful supply of pure water cannot be overrated. For domestic purposes, such as cooking and washing, and for manufacturing purposes, such as distilling, brewing, tanning, dyeing, starch making, paper making, and chemical works, the main use of water is as a solvent. Anything, therefore, which detracts from its solvent powers, must more or less unfit it for the purposes above referred to. It is well known that hard water requires more soap to wash with—that it necessitates the use of more tea and coffee to make our everyday beverages—more meat to produce soups and gravies—more malt to give us spirits and beer—more bark for tanning extract—and more chemicals for producing the various extracts—than would be required were perfectly pure, or at least soft water, used. The actual loss from these sources must be something enormous, amounting to many million pounds sterling per annum.

For many manufacturing purposes, such as bleaching, paper making, &c., it is also necessary that the water used should be perfectly free from colour; consequently, where traces of iron or decomposed organic matter are present, they must either be removed or some other source of supply sought out. Great expense is often gone to in sinking Artesian wells, or conveying pure water from a long distance, where no real necessity for such outlay exists. And for the domestic and manufacturing purposes enumerated, it may safely be affirmed, that no natural water is so pure as not to be capable of great improvement by a judicious system of filtration and purification.

After some clear remarks upon the different kinds of impurities present in water and the various means adopted for their separation, the author continues:—

"A water purifying apparatus, then, should be able to act upon the impurities held in solution as well as those

in mechanical suspension. It should be composed of materials incapable of giving any taint to the water passing through it. Its action should be rapid and effective. Its operation attended with the least possible trouble, or necessity for attention on the part of servants. It should be capable of retaining its purifying properties for a lengthened period. It should be so arranged that the filtering medium may be easily got at for cleansing or renewal. And, finally, the price should be such as to place it within the reach of all classes in the community."

It is scarcely necessary for us to state that this is followed by an assurance that the filters made according to Mr. Danchell's plan more than fulfil all the above conditions. Whether this be the case or not, we have had no opportunity of judging, but it is only fair to say that the material upon which he mainly relies as a purifying agent is about the best that could be employed, and that the style in which the little work is written shows that the author thoroughly understands the subject of water purification.

NOTICES OF PATENTS.

Manufacture of Gas. JOHN LESLIE. (Two Patents.)

THESE two patents are of great commercial importance. The first patent has for its object improvements in the manufacture of gas. Heretofore in manufacturing gas from coal and other bituminous mineral substances it has been usual to subject them to the process of destructive distillation, and then to purify the gas obtained. These improvements in the manufacture of gas for the purposes of illumination from Parrot coal, Cannel coal, Boghead coal, and other mineral bituminous matters capable of affording paraffine, consist in subjecting such mineral bituminous matters to distillation at low temperatures, in order to obtain the products distilled over in a condensed liquid form, and then to subject such liquids to processes of purification, in order to fix or remove the ammonia, sulphur, and other impurities, and then to subject the purified liquids to destructive distillation, by which very pure gas is obtained.

In the manufacture of gas from coal by destructive distillation as at present practised in gas works, it is necessary to employ very extensive, and at the same time, very expensive machinery and processes between the retorts where the gas is distilled off and the gasometers wherein the gas is stored for distribution, and the necessity for the use of such machinery and processes arises from the high temperatures employed in distilling over every vaporizable constituent of the coals employed, by which not only is the illuminating gas distilled off, but also very inferior and deteriorating gases, with products of sulphur and other impure matters, which are prejudicial not only in respect to the illuminating powers of the combined gases, but they are also injurious in other respects. And it is for the purposes of purifying the gases from the sulphur and other impure products that gas works have heretofore found it necessary to employ such extensive and expensive machinery and processes. In addition to the above objections, large quantities of tar, as well as of very offensive products, result from the present system of manufacturing gas from coal at gas works, resulting in a great waste in regard to the quantity of good and pure illuminating gas a given weight of coal is capable of affording. According to this invention illuminating gas may be manufactured from coal and other bituminous mineral in such manner as to dispense with the use of the machinery and processes now necessary in gas works for purifying the gases after they leave the retorts, and before they arrive at the gasometers. It

consists in so arranging gas works as to employ in the manufacture of gas the hydrocarbon products of coal or other bituminous minerals obtained by distilling such substances at a low temperature, whereby the patentee is enabled to dispense with the machinery and processes used for purifying illuminating gas obtained by the existing process of destructive distillation of the bituminous mineral; for these purposes Cannel coal, parrot coal, Boghead coal, and other coal, and other mineral bituminous matters, are distilled at a low temperature, in such manner as to obtain the products in a condensed form in place of in the state of gases; then, when necessary, the resulting fluids are purified, and then such fluids are subjected to the action of heat in a finely divided state in retorts or vessels, to convert them into gas, which is conveyed into gasometers such as heretofore used at gas works, in order that the same may be distributed therefrom, as heretofore practised.

Mr. Leslie prefers to use a cylindrical retort heated externally by a fire, such retort being caused constantly to revolve slowly. Into this the coal or bituminous mineral is introduced, broken up into small pieces, and the products evolved pass off to the condensing apparatus, which is constantly kept cool by water, and the condensed hydrocarbon products are received into a suitable receiver or vessel. Care is to be taken to keep down the heat of the retort, in order to prevent the production of gas or vapours which will not condense, the object being to obtain only fluid hydrocarbons by the first process of distillation.

When using the better classes of Cannel coal, the hydrocarbons obtained may at once be employed for the manufacture of gas, but when using hydrocarbons (obtained from less pure coal or other bituminous mineral) which have nitrogenous and sulphur compounds combined therewith, these are purified in the following manner:—To remove the nitrogen the crude hydrocarbons are washed with dilute acid; dilute sulphuric acid will answer the purpose, but dilute muriatic acid is preferable prepared by adding five gallons of water to one gallon of the concentrated muriatic acid of commerce; the hydrocarbons are then agitated violently with this diluted acid, using 15 gallons of the diluted acid to every ton of the oil. The mixed hydrocarbons and acid is then allowed to stand for twelve hours, at a temperature of 90° to 100° Fahrenheit, and then the layer of acid liquor which will have separated must be drawn off. To free the hydrocarbons from sulphur compounds, the patentee uses at the rate of 1 lb. caustic soda with 1 gallon of water, and from 14 to 30 gallons of such solution will be found sufficient to purify a ton of the hydrocarbon fluid; for this purpose the solution is well stirred into the hydrocarbons, and then allowed to settle for some hours, when the purified hydrocarbons may be readily drawn off from the impurities.

In order to convert the hydrocarbon liquid into illuminating gas, it is caused to drop into a retort or vessel heated to a good red heat, and the gas is conveyed from the retort into gasometers of the ordinary construction, from which the illuminating gas is supplied to the gas mains, as gas has heretofore been supplied from gasometers.

By these improvements not only will gas works be rendered less objectionable in any neighbourhood, but the gas obtained will be more pure, and the cost of production will be greatly reduced.

The second patent has principally for its object the purification of gas after it is manufactured. For these purposes, in distilling coal or other substance, the gas, in place of being conducted off from the upper part of the retort, and thence into the hydraulic main, is caused to descend from the retort at the lower part thereof into a chamber, and thence the gas is conducted off by a pipe at the upper part of the chamber to purifiers. Several

retorts may be connected with the same chamber, in which case they each have a slide or other valve to shut the entrance into the chamber. And in purifying gas, a solution of a salt of copper, preferring the sulphate, is employed to saturate wood shavings or other porous material, through and amongst which the gas is caused to pass. The purifying matters thus employed are from time to time subjected to the passage of atmospheric air amongst them to re-prepare them for the further purification of gas therewith.

By the kindness of the Patentee we have been enabled to witness some of the remarkable results which are obtained by these processes. A weighed quantity ($2\frac{1}{2}$ lbs.) of Boghead coal was placed in a retort, which was kept slowly revolving over a fire, the temperature never approaching a red heat, and, indeed, scarcely reaching that of melting lead. The slow rotation of the retort preventing any one portion of the coal from becoming hotter than the rest, the volatile constituents were all evolved in the liquid form, no gas whatever being produced. In a short time the $2\frac{1}{2}$ lbs. of coal had yielded in the receiver $1\frac{1}{2}$ pints of hydrocarbon fluid, leaving $\frac{1}{2}$ lb. of coke in the retort. As soon as the liquid had ceased to come over, it was carried to an iron retort which was kept at a red heat by means of a furnace, the arrangement being similar to that employed in gas-works. The $1\frac{1}{2}$ pints of hydrocarbon fluid was then allowed to drop through a funnel tube into this red-hot retort, when the gas-holder which was in connexion with it instantly began to rise, and within a minute and a-half 25 cubic feet of gas had come into the holder. The next day the luminosity of the gas, which we had seen prepared, was ascertained by means of a photometer. When burning at the rate of four feet per hour, it equalled twenty sperm candles.

The remarkable character of these results becomes more apparent if we calculate by the ton instead of the pound. A yield of $1\frac{1}{2}$ pints for every $2\frac{1}{2}$ lbs. of coal is equivalent to 168 gallons per ton of 2240 lbs. Now 168 gallons is almost exactly one cubic yard, and calculating each gallon to produce, almost instantaneously, 128 cubic feet of gas, we have thus 21,504 cubic feet of gas from 168 gallons, the material for the production of which only occupying one cubic yard of space.

Besides the greatly-increased yield obtained by this process, there are other advantages which recommend it to the serious consideration of Gas Companies. By its means all the refuse coal which is now completely wasted at the pit's mouth may be distilled into oil at the collieries. This fluid may be further purified from sulphur and other deleterious substances on the spot where it is made, whence it could be carried up to London, and converted into gas in the space of a few minutes. The advantages of this would be: the coal being used at the pit's mouth would cost a mere trifle; all the troublesome work of distillation and purification, with its concomitant evils of poisoning the neighbourhood by the offensive odour, could be performed where labour was cheap, and ground plentiful, instead of as at present in the heart of London; the expense of carriage of material to London would be considerably reduced, as only the real gas-making constituent of the coal would be transported; and lastly the complicated machinery of plant and hands, with the sickening odour with which it is always surrounded, would be in great measure done away with, no purifying apparatus being needed, and the mechanical labour of converting any quantity of the hydrocarbon fluid into gas, being reduced to the capacity of "a man and a boy."

Pigments for Coating Surfaces. G. HALLETT and J. STENHOUSE.

This invention consists in the employment of the oxides of antimony, either native or artificially prepared, as

pigments suitable for out-door application, and to be used in much the same manner as white lead. For the preparation of their material the patentees employ at once the native oxide, or that kind of mineral in which a certain quantity of the sulphide of antimony is associated with the oxide. These are crushed to a tolerably fine powder, and purified from the gangue or matrix by mechanical sorting and washing. The heavy ore is dried and subjected to the process of calcination or roasting in a reverberatory furnace with a plentiful supply of air, during which treatment all the sulphur is expelled, and the residual metal converted for the most part into antimonious acid. The calcined product requires to be very finely ground, and mixed with any suitable oil or varnish to form the paint.

In the preparation of antimonial oxides from ores or metallic regulus there is a tendency for the product to become slightly discoloured by the presence, in small quantities, of other metallic oxides (e.g., those of lead, copper, and iron), traces of either of which common impurities operate powerfully in darkening the shade of colour possessed by the pure oxide of antimony. On this account the antimony paint would not be so suitable as zinc or white lead for application whenever purity of tint is desired; but would, nevertheless, seem well adapted for the preparation of stone colour. In all cases where the painted surface would afterwards be liable to the action of an atmosphere impregnated with sulphuretted hydrogen the antimonial stone colour would, in comparison with lead, have the advantage. Although possessing more body than zinc paint, it does not appear to be, in this respect, equal to white lead.

An Impermeable Protective Coating for Leather.

C. STEVENS. A Communication. (Not proceeded with.)

This proposition relates to the employment of gutta-percha and india-rubber, severally dissolved in bisulphide of carbon, for the purpose of coating leather, and thereby rendering it less liable to become deteriorated by the action of the acids usually present in common blacking. Saturated solutions are preferred; that containing india-rubber is recommended to be first applied.

The advantage of employing the bisulphide of carbon in preference to other cheaper and more agreeable solvents for making the varnishes is not very manifest, unless on the assumption that the agent described in the specification must appear to possess the charm of novelty.

CORRESPONDENCE.

Bisulphide of Carbon in Gas.

To the Editor of the CHEMICAL NEWS.

SIR,—My Report on "Bisulphide of Carbon in Gas" has been honoured with such marked notice in the last two numbers of your Journal, that I am obliged to request the favour of the insertion of this letter.

Any writer of an ordinary pamphlet must expect to have his composition criticised, and must submit to be abused or complimented, as the case may be. I therefore ought to be highly flattered on seeing that so much notice has been taken of the Report in question; and I could well afford to let your articles pass unnoticed if my silence would not be taken as a confirmation of the statements made in your pages, and if the articles had been merely simple criticisms. But when I find that experiments have been made, the result of which have been placed in juxtaposition to mine, evidently for the sole purpose of confuting them, I feel justified, before entering into the merits or demerits of either, to ask through you the name of the author of the articles.

I shall be very pleased to accept the challenge implied, but before doing so certainly may expect in fairness my request acceded to, especially as my experiments were vouched for by the attachment of my signature.

I therefore again request to know who is the "we" who has made the "independent examination" from which such wonderful numbers have been deduced, and who seems to possess the peculiar facility of casting insinuations repugnant to the minds of scientific and honourable men.

I am, &c.

FRED. VERSMANN, F.C.S.

Chemical Laboratory, 7, Bury Court, St. Mary Axe, July, 1861.

[The Editor's name is printed on each number of the *CHEMICAL NEWS*, and he takes the responsibility of all Editorial articles. We cannot see that Mr. Versmann has anything to complain of. Far from wishing to cast insinuations to which he, as a scientific and honourable man, could object, we took particular pains in each notice to assure our readers that we did not intend to question the perfect accuracy of Mr. Versmann's results.—Ed. C. N.]

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Explosion in Making Phosphoric Acid.—Elsner relates (*Chem. tech. Mittheilungen*, 1859-60, s. 121) that some time since as a chemist was making phosphoric acid, by acting on phosphorus with nitric acid in a retort, a tremendous explosion took place when the mixture was heated, which not only shattered the retort but blew out all the windows, and even shook the walls of the laboratory. The cause of the explosion he supposes to be the formation of phosphuretted hydrogen from the sudden decomposition of vapour of phosphorous acid into that gas and phosphoric acid. Elsner recommends that the phosphorus should be treated with nitric acid in a large dish, so that the vapour of phosphorus acid may have free escape.

Behaviour of Sulphurous to Iodic Acid.—Dr. H. Kaemmerer describes (*Journal für prakt. Chemie*, Bd. lxxxiii. s. 72) an hitherto unobserved reaction of sulphurous on iodic acid. He took finely powdered anhydrous iodic acid and acted on it for some time by dry sulphurous acid. When the action had continued a quarter or half-an-hour, decomposition commenced, and a small quantity of iodine was set free, which escaped from the exit tube with the sulphurous acid. Immediately afterwards the remaining iodic acid suddenly became of a bright yellow colour, having formed, says the author, the compound $5\text{IO}_5 + \text{SO}_2$. This body must be quickly placed in a perfectly dry bottle, as it soon decomposes in the air.

If the action of the SO_2 be continued longer, rapid decomposition ensues, much iodine separates, and the mass collects together in small lumps, which adhere to the tube. From these free iodine and sulphuric acid may be washed out by alcohol and water, and then there will be left a new compound of iodine and oxygen I_2O_{13} , with a small percentage of SO_2 , which it is difficult to remove.

The *sulpho-iodic acid anhydride* $5\text{IO}_5 + \text{SO}_2$ has a beautiful bright yellow colour, a granular appearance, and the remarkable property of decomposing in contact with water, iodine being separated. In absolute alcohol and in ether it simply splits into IO_5 and SO_2 , forming in an alcoholic solution of potash iodate and sulphate of potash.

The new compound I_2O_{13} is a brown yellow powder, which does not change in the air, but always takes up some water. It dissolves in dilute nitric acid with the separation of iodine; fuming nitric acid oxidises it to IO_5 ; water at the ordinary temperature decomposes it slowly; boiling water splits it up immediately into I and

IO_5 . Heated alone to 100° it breaks up in the same way: $5\text{I}_2\text{O}_{13} = 13\text{IO}_5 + 2\text{I}$.

Aqueous solutions of the alkalies decompose the new compound, forming iodates of the alkalies and setting free iodine. Alcoholic solutions have no action on the compound, nor have absolute alcohol, ether, acetic ether, or sulphide of carbon, either at the ordinary temperature or at their boiling points.

New Oxychloride of Bismuth.—M. Lebaigue has obtained a compound to which he attributes the formula $(\text{Bi}_2\text{Cl}_3)_2 \cdot 2\text{Bi}_2\text{O}_3$ (*Journal de Pharm. et de Chim.*, Tome xxxix., p. 108). He treated oxide of bismuth with sulphuric acid, heated the mass until no more acid vapour was given off, mixed the yellowish powder obtained with twice its weight of fused chloride of sodium, and placed the mixture in a clay retort set in a reverberatory furnace. After keeping the retort red hot for some time, he was surprised to find that nothing distilled. He then allowed it to cool, broke the retort, and found a fused mass, which treated with water broke up into the soluble acid chloride and insoluble sub-chloride. Mixed with the latter were some brilliant white scales, which the author carefully separated and analysed. The results led the author to believe that the scales were formed of new oxychloride of bismuth, having the formula $(\text{Bi}_2\text{Cl}_3)_2 \cdot 2\text{Bi}_2\text{O}_3$.

II. ORGANIC CHEMISTRY.

New Acid from Toluol.—Fittig gives (*Annal. der Chem. und Pharm.*, Bd. cxvii. s. 191) a preliminary notice of a new acid he has discovered in the oxidation of toluol by nitric acid. It is colourless, perfectly insoluble in cold water, and only slightly soluble in hot water. At a higher temperature it fuses and sublimes undecomposed. It appears to have the same composition as salicylic acid without being identical, for it does not give the reaction of salicylic acid with chloride of iron. The baryta salt is easily soluble in water, and crystallises from the solution in warty tufts. The analysis of the crystals gave 32.7 per cent. Ba. The formula $\text{C}_{14}\text{H}_8\text{BaO}_6$ requires 33.3 per cent. Ba.

III. ANALYTICAL CHEMISTRY.

New Test for Sulphurous Acid.—A solution of nitroprusside of sodium, added to a solution of sulphite of soda, gives a pale rose colour, which is much more distinct when an excess of sulphate of zinc has previously been added to the solution of nitroprusside; but an intense purple red is produced when a small quantity of yellow prussiate of potash is added to the mixture. This reaction may be applied to the detection of sulphurous acid in the following way:—If the substance to be tested is soluble in water, but not neutral, it is first neutralised with acetic acid or bicarbonate of soda; an excess of the latter is not objectionable, but an excess of either caustic or carbonate of soda, or of carbonate of ammonia, prevents the reaction. If any bases are present which give insoluble salts with sulphurous acid, these must be removed. Then a proportionately large quantity of solution of sulphate of zinc is mixed with a very small quantity of nitroprusside of sodium, and added to the solution to be tested. When the amount of sulphurous acid present is not too small, a rose red or dark red colour is soon produced; but if it is not very distinct, the addition of some yellow prussiate will give an intense red. In this way a most minute quantity of sulphurous acid may be detected. Hyposulphurous acid, and hyposulphites of the alkalies, under the same circumstances, produce no reaction.—C. Boedeker. *Annal. der Chem. und Pharm.* Bd. cxvii. s. 193.

IV. TECHNICAL CHEMISTRY.

Adulteration of Wax with Paraffine.—Ludolt has met with a specimen of wax adulterated with paraffine. He detected the adulteration in the following way

Dingler's Polytech. Journal, Bd. clx. s. 224) :—He heated a piece of the wax with an excess of fuming sulphuric acid. When the wax melted a strong action took place, and when the evolution of vapour ceased the heat was continued a little longer, and then the mixture was allowed to cool. After cooling, the paraffine was found as a transparent layer upon the sulphuric acid. So much sulphuric acid must be used, that when the operation is ended the black residue may be fluid, otherwise it is difficult to separate the paraffine. Very small quantities of paraffine, the author says, may be discovered in this way. English sulphuric acid is not convenient for the purpose, as it decomposes the wax but slowly.

MISCELLANEOUS.

For Regularly Cracking Glass, a very expeditious plan is to use a pearl of glass melted with some soda on a platinum wire, heated before the blowpipe; the crack having been previously started with a sharp blade of first-rate cast-steel, made diamond-hard by quickly cooling.—*Dr. L. C. Levoir.*

Coal in California.—We learn from the *Californian Mining and Scientific Press* that a meeting of the members of the California Academy of Sciences, was held in San Francisco on May 15, at which Professor Blake gave an interesting description of the coal regions of Monte Diablo, accompanied with specimens of the coal. The veins are rather thin, but the coal is good bituminous. The fossils of the region belong to the tertiary formations. Professor Whitney is of opinion that the coal was formed from accumulations carried by eddies, and deposited in still water. A considerable quantity of this coal has been taken to San Francisco, and it has tended to reduce the price of wood and the foreign coal. A plentiful supply of coal in California would tend greatly to facilitate quartz-mining, by enabling the machinery to be operated by cheap steam power. Coal will also make California a great manufacturing State.

The Healthfulness of Fresh Paint in Apartments.—M. Leclerc, a well-known house-painter in Paris, has lately made some experiments to ascertain whether emanations from certain paints containing such substances as white lead, zinc white, linseed oil, essence of turpentine, coal oil, essence of lavender, &c., are injurious to health. He caused the insides of some boxes to be painted, and within them he placed wire cages containing rabbits which were not in contact with the paint but only subject to the influence of the emanations from it. The rabbits suffered while the paint was fresh, especially when it contained coal oil, but none of them died. It is thus proved that living in apartments recently painted, and which emit the odour of the oil of turpentine is not permanently injurious to health. M. Leclerc made, also, some other experiments for the purpose of obtaining deposits of these emanations from the fresh paintings of houses. Instead of rabbits he placed plates containing a small quantity of water in these chests. After the water had evaporated from the plates, he found some remarkable crystallisations like needles, which consisted of combinations in which the oils or essences employed formed the principal part. These crystalline combinations were obtained even when linseed oil was used. M. Deville had previously obtained similar crystallisations, but under entirely different circumstances. After these experiments and their results had been explained to the Academy of Sciences, M. Chevreul added that M. Leclerc had opened a new path of discovery for scientific men, which even Chemists might follow with profit.—*Mechanics' Magazine.*

British Association for the Advancement of Science.—The thirty-first meeting of the British Association for the Advancement of Science will commence in Manchester on Wednesday, September 4, 1881, under the presidency of William Fairbairn, Esq., LL.D., F.R.S. The General Committee will meet on Wednesday, September 4, at one a.m., for the election of sectional officers and the despatch of business usually brought before that body. On this occasion there will be presented the Report of the Council, embodying their proceedings during the past year. The general committee will meet afterwards by adjournment. The first general meeting will be held on Wednesday, September 4, at eight p.m., when the President will deliver an address; the concluding meeting on Wednesday, September 11, at three p.m., when the Association will be adjourned to its next place of meeting. At two evening meetings, which will take place at eight p.m., discourses on certain branches of science will be delivered. There will also be other evening meetings, at which opportunity will be afforded for general conversation among the members. The committees of Sections will meet daily from Thursday, September 5, to Tuesday, September 10, inclusive, at ten a.m., precisely. The following are the titles of the sections to which communications may be presented :—Section A. Mathematics and Physics; Section B. Chemistry and Mineralogy, including their Applications to Agriculture and the Arts; Section C. Geology; Section D. Zoology and Botany, including Physiology, sub-section D.; Section E. Geography and Ethnology; Section F. Economic Science and Statistics; Section G. Mechanical Science. Notices or communications intended to be read to the Association, accompanied by a statement whether the author will be present or not at the meeting, may be addressed to Professor Phillips, M.A., LL.D., F.R.S., Assistant-General Secretary, University Museum, Oxford; or to R. D. Darbishire, Esq., B.A., F.G.S., Alfred Neild, Esq., Arthur Ransome, Esq., M.A., and Professor Roscoe, B.A., Local Secretaries, Manchester. Gentlemen desirous of attending the meeting will find in the reception room (the Portico, in Mosley Street) blank forms of proposal, and may make their choice of being proposed as life members, paying ten pounds as a composition, or annual subscribers, paying one pound annually and an admission fee of one pound (making together two pounds on admission); or associates for the meeting, paying one pound. Ladies may obtain tickets, through the application of a member, in the reception-room, price one pound each ticket. These tickets are transferable to other ladies only.

ANSWERS TO CORRESPONDENTS.

* All Editorial Communications are to be addressed to the Editor; and Advertisements and Business Communications to the Publisher at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

N. T.—Mr. Perkin's address is Greenford Green, Sudbury, N.W.

H. C. S. E.—We will propose you, if you wish to become a Member.

Titanic Acid.—*F. S.*—To detect this acid in the presence of silicic acid, treat the silicic acid with hydrofluoric acid. Fuse the residue with metallic zinc and microcosmic salt; after the combustion of the zinc and clearing of the lead, on cooling, a very distinct colouration is always produced, whereas the button of microcosmic salt and titanitic acid gives no reaction in the ordinary way. By this test (which is recommended by Riley) titanitic acid may be found in pig iron.

Specific Gravity writes as follows :—"Would it be possible in the quantitative analysis of waters, having obtained the specific gravity, to calculate thence the total amount of solid matter contained in any volume? Hence, suppose the s. g. of a sample of water to be 1.004, the weight of an Imperial gallon of such water would be $1.004 \times 70,000 = 70,280$ grs. Now, as an Imperial gallon of distilled water is 70,000 grs., is not the amount of solid matter contained in one gallon of the water under examination the difference in weight = 280 grs.? If this is the case, it saves the long and tedious operation of evaporating down to obtain the same result. And *vice versa*, knowing the weight of the total solid contents, cannot you calculate the s. g."

THE CHEMICAL NEWS.

VOL. IV. No. 89.—August 17, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Gerhardt's Equivalents and Notation.

(Continued from vol. iii. p. 373.)

FURTHER examples, illustrating the relations between the atomic weights of compounds and their specific gravities, are given in the following table:—

Name of Substance.	Formula.	Atomic weight.	Specific gravity of vapour.	Atomic volume.
Carbonic oxide . . .	CO	28	13.950	2
Carbonic anhydride . .	CO ₂	44	21.973	2
Phosgene gas . . .	COCl ₂	99	49.931	2
Bisulphide of carbon .	CS ₂	76	38.121	2
Sulphurous anhydride .	SO ₂	64	32.031	2
Sulphuric anhydride .	SO ₃	80	43.243	2
Phosphoretted hydrgn.	H ₂ P	34	16.792	2
Trichloride of arsenic	AsCl ₃	181.5	90.819	2
Ethyl-alcohol . . .	C ₂ H ₅ O	46	23.254	2
Ethyl-ether . . .	C ₂ H ₅ O	74	36.973	2
Methyl-ethyl-ether . .	C ₃ H ₇ O	60	31.005	2
Acetic acid . . .	C ₂ H ₃ O ₂	60	30.558	2
Acetic anhydride . .	C ₂ H ₃ O ₂	102	50.018	2
Acetate of ethyl . .	C ₂ H ₃ O ₂	88	44.209	2
Aldehyde . . .	C ₂ H ₃ O	44	22.082	2
Ethylene . . .	C ₂ H ₄	28	14.131	2
Marsh gas . . .	CH ₄	16	8.038	2
Chloroform . . .	CHCl ₃	119.5	60.539	2
Tetrachloride of carbon	CCl ₄	154	76.828	2
Camphor . . .	C ₁₀ H ₁₆ O	152	76.604	2
Ethylamine . . .	C ₂ H ₇ N	45	22.630	2

The relation between atomic weight and specific gravity in the state of vapour (vapour density) which we have pointed out, has been so uniformly observed, that chemists are inclined to doubt the exactitude of the formulæ of all compounds the atomic weight of which does not yield two volumes of vapour, and the determination of the vapour density of a compound has thus become one of the most important means of controlling chemical formulæ.

The discrepancy in the vapour volumes furnished by the elementary and compound atoms, the former corresponding, as has been pointed out, to one volume, while the latter represent two volumes, has led Gerhardt to the revival of a hypothesis which had been previously countenanced by several inquirers. This hypothesis assumes that the elementary atoms are incapable of existing in the free state, and that whenever elementary atoms are liberated they combine, so to say, with themselves, and separate in pairs, which pairs of atoms may be called the molecules of the elements. We thus arrive at a rigorous distinction between the terms representing the smallest quantities in which the elements enter into combination; the latter the smallest quantity of an element capable of existing in a free state.

The molecules of the elements possessing, as they do, the double weight of the atoms, correspond, with the exception of phosphorus and arsenic (see p. 702), to 2 volumes of gas or vapour.

Name of Element.	Specific gravity.	Atomic weight.	Atomic volume.	Molecular weight.	Molecular volume.
Hydrogen .	1	H 1	1	HH 2	2
Oxygen .	16	O 16	1	OO 32	2
Sulphur .	32	S 32	1	SS 64	2
Chlorine .	35.5	Cl 35.5	1	ClCl 71	2
Bromine .	80	Br 80	1	BrBr 160	2
Iodine .	127	I 127	1	II 254	2
Nitrogen .	14	N 14	1	NN 28	2
Phosphorus	62	P 31	1	PP 62	1
Arsenic .	150	As 75	1	AsAs 150	1
Mercury .	100	Hg 100	1	HgHg 200	2

It is thus seen that the molecules of the elements, like the atoms of compounds, correspond to 2 volumes of vapour, and that if we adopt for the elements the double symbols as designating the molecules, all chemical formulæ, with the exception of those of phosphorus and arsenic, represent weights of matter simple or compound, which in the state of gas or vapour occupy the same volume.

The assumption that the elementary molecules consist of two atoms, is not capable of being proved directly, but it is supported by many considerations and analogies which are chiefly taken from organic chemistry. The limits of this outline will only admit the chief argument to be mentioned here.

The researches of the last ten or twelve years have led to the preparation of a series of hydrocarbons, which are considered as the radicals of the alcohols. The radicals methyl, ethyl, propyl, butyl, amyl, and caproyl have been successively examined. The composition of the alcohols to which these radicals belong, being—

Methylic alcohol (C₁H₃) HO,
 Ethylic alcohol (C₂H₅) HO,
 Propylic alcohol (C₃H₇) HO,
 Butylic alcohol (C₄H₉) HO,
 Amylic alcohol (C₅H₁₁) HO,
 Caproylic alcohol (C₆H₁₃) HO,

nothing appeared more justifiable than the formulæ,—

C₁H₃ for methyl, C₄H₉ for butyl,
 C₂H₅ for ethyl, C₅H₁₁ for amyl,
 C₃H₇ for propyl, C₆H₁₃ for caproyl,

which were originally proposed for these hydrocarbons. A more minute examination of these compounds, however, very soon led chemists to double these formulæ. It is only thus that they represent quantities yielding 2 volumes of vapour, like all other compounds, and that the differences of boiling-point exhibited by these substances are made to accord with the experience on boiling-points derived from numerous other observations. In the following Table the formulæ, atomic weights,

vapour-densities, atomic volumes, and boiling-points of the six substances in question are united:—

Name.	Formula.	Atomic weight.	Sp. gr. of vapour.	Atomic volume.	Boiling point.
Methyl	$\text{C}_2\text{H}_6 = (\text{CH}_3)(\text{CH}_3)$	30.15	2	Unknown.	
Ethyl	$\text{C}_4\text{H}_{10} = (\text{C}_2\text{H}_5)(\text{C}_2\text{H}_5)$	58.29	2	Unknown.	
Propyl	$\text{C}_6\text{H}_{14} = (\text{C}_3\text{H}_7)(\text{C}_3\text{H}_7)$	86.43	2	$154^\circ.4$, 68°C .	
Butyl	$\text{C}_8\text{H}_{18} = (\text{C}_4\text{H}_9)(\text{C}_4\text{H}_9)$	114.57	2	$226^\circ.4$, 108°C .	
Amyl	$\text{C}_{10}\text{H}_{22} = (\text{C}_5\text{H}_{11})(\text{C}_5\text{H}_{11})$	142.71	2	$311^\circ.0$, 155°C .	
Caproyl	$\text{C}_{12}\text{H}_{26} = (\text{C}_6\text{H}_{13})(\text{C}_6\text{H}_{13})$	170.85	2	$395^\circ.6$, 202°C .	

The difference between the boiling-points of propyl and butyl is $226^\circ.4 - 154^\circ.4 = 72^\circ.0$ ($108^\circ - 68^\circ = 40^\circ \text{C}$); that between the boiling-points of butyl and amyl, $311^\circ - 226^\circ.4 = 84^\circ.6$ ($155^\circ - 108^\circ = 47^\circ \text{C}$); and lastly, the difference between the boiling-points of amyl and caproyl, $395^\circ.6 - 311^\circ = 84^\circ.6$ ($202^\circ - 155^\circ = 47^\circ \text{C}$).

According to Kopp's observations, an increment of $\text{C}_2\text{H}_2 = \text{CH}_2$ in composition raises the boiling-point $36^\circ.3 = 19^\circ.9 \text{C}$. (see p. 499.) The boiling-points of propyl, butyl, amyl, and caproyl unmistakeably show that these bodies differ in composition not by CH_2 as implied in the formulæ

but by

as implied by the formulæ,—

If methylic, ethylic, propylic, butylic, amylic, and caproylic alcohols be viewed as water in which one atom of hydrogen is replaced respectively by the compound atoms

methyl C_2H_5 , ethyl C_3H_7 , butyl C_4H_9 , amyl C_5H_{11} , and caproyl C_6H_{13} ,

it becomes probable, from the boiling-point relations alluded to, that the compound atoms

in the moment of their liberation, combine with themselves, giving rise to what we may now call the compound molecules,

The methyl-, ethyl-, propyl-, &c., atoms, such as exist in the alcohols, correspond to the atom of hydrogen (to $\text{H} = 1$) such as we assume it to exist in combination. The methyl-, ethyl-, propyl-, &c., molecules which exist in the free state, consisting, as they do, of two atoms of these radicals, correspond to the molecule of hydrogen, which consists itself of two atoms of hydrogen.

(To be continued.)

*On Liquid Diffusion Applied to Analysis,*¹
by T. GRAHAM, Esq., F.R.S., Master of the Mint.

THE unequal diffusibility of different substances in water appears to present means of separation not unlike those long derived from unequal volatility. For, as regards diffusion, there exists a "volatile," and also a "fixed" class of substances; and these distinctions appear to correspond with differences in molecular constitution of a fundamental nature. Much value is attached to diffusion, as affording the means of bringing out clearly, and subjecting to numerical expression, the distinctive properties of what appear to be two great divisions of chemical substances.

The first, or *diffusive* class of substances, are marked by their tendency to crystallise, either alone or in combination with water. When in a state of solution they are held by the solvent with a certain force, so as to effect the volatility of water by their presence. The solution is generally free from viscosity, and is always sapid. Their reactions are energetic and quickly effected. This is the class of *crystalloids*.

The other class, of low diffusibility, may be named *colloids*, as they appear to be typified by animal gelatine. They have little if any tendency to crystallise, and they affect a vitreous structure. The planes of the crystal with its hardness and brittleness are replaced in the colloid by rounded outlines with more or less softness and toughness of texture. Water of crystallisation is represented by water of gelatination. Colloids are held in solution by a feeble power, and have little effect on the volatility of the solvent. They are also precipitated from their solution by the addition of crystalloids. The solution of colloids has always a certain degree of viscosity or gumminess when concentrated. They appear to be insipid, or wholly tasteless, unless when they undergo decomposition upon the palate and give rise to sapid crystalloids. Their solid hydrates are gelatinous bodies. They are united to water with a force of low intensity; and such is the character of the combinations in general between a colloid and a crystalloid, even although the latter may be a powerful re-agent in its own class, such as an acid or an alkali. In their chemical reactions, the crystalloidal appears the energetic form, and the colloidal the inert form of matter. The combining equivalent of the colloid appears always to be high, and it has a heavy molecule. Among the colloids rank hydrated silicic acid, and a number of soluble hydrated metallic peroxides, of which little has hitherto been known; also starch, the vegetable gums and dextrin, caramel, tannin, albumen, and vegetable and animal extractive matters. The peculiar structure and chemical indifference of colloids appear to adapt them for the animal organisation, of which they become the plastic elements.

Although the two classes are widely separated in their properties, a complete parallelism appears to hold between them. Their existence in Nature appears to call for a corresponding division of chemistry into a crystalloid and a colloid department.

Although chemically inert in the ordinary sense, colloids possess a comparative activity of their own, arising out of their physical properties. While the rigidity of the crystalline structure shuts out external impressions, the softness of the gelatinous colloid partakes of fluidity, and enables the colloid to become a medium for liquid diffusion, like water itself. The same

¹ Read before the Royal Society, June 6th, 1861.

penetrability appears to take the form of a capacity for cementation in such colloids as can exist at a high temperature. Hence a wide sensibility on the part of colloids to external agents. Another eminently characteristic quality of colloids is their mutability. Their existence is a continued metastasis. A colloid may be compared in this respect to water while existing liquid at a temperature below its usual freezing point, or to a supersaturated saline solution. The solution of hydrated silicic acid, for instance, is easily obtained in a state of purity, but cannot be preserved. It may remain fluid for days or weeks in a sealed tube, but is sure to gelatinise at last. Nor does the change of this colloid appear to stop at that point; for the mineral forms of silicic acid deposited from water, such as flint, are found to have passed, during the geological ages of their existence, from the vitreous or colloidal into the crystalline condition (H. Rose). The colloidal is, in fact, a dynamical state of matter; the crystalloidal being the statical condition. The colloid possesses *energia*. It may be looked upon as the probable primary source of the force appearing in the phenomena of vitality. To the gradual manner also in which colloidal changes take place—for they always demand time as an element—may the chronic nature and periodicity of vital phenomena be ultimately referred.

For the separation of unequally diffusive crystalloids from each other, jar-diffusion was had recourse to. The mixed solution was conveyed by means of a pipette to the bottom of a column of water contained in a cylindrical glass jar. A kind of cohabitation takes place, a portion of the most diffusive substance rising and separating from the less diffusive substances, more and more completely as it ascends.

The separation of a crystalloid from a colloid is more properly effected by a combination of diffusion with the action of a septum composed of an insoluble colloidal material. Animal membrane will serve for the latter purpose, or a film of gelatinous starch, hydrated gelatin itself, albumen, or animal mucus. But by much the most effective septum used was paper, as it is metamorphosed by sulphuric acid (Gaine). It is now supplied by Messrs. De La Rue, and has become familiar under the name of "vegetable parchment," or "parchment paper." From sheet gutta percha a flat hoop is formed, eight or ten inches in diameter by three inches in depth, and one side is covered by a disc of parchment paper, so as to form a vessel like a sieve. A mixed solution, which may be supposed to contain sugar and gum, is placed upon the septum to a depth of half-an-inch, and the instrument then floated upon a considerable volume of water contained in a basin. Three-fourths of the sugar diffuses out in twenty-four hours, and so free from gum as to be scarcely affected by subacetate of lead, and to crystallise on the evaporation of the external water by the heat of a water-bath.

The unequal action of the septum, which causes the separation described, appears to depend upon this:—The crystalloid sugar is capable of taking water from the hydrated colloidal septum, and thus obtains a medium for diffusion; but the colloid gum has little or no power to separate the combined water of the same septum, and does not, therefore, open the door for its escape by diffusion, as the sugar does. This separating action of the colloidal septum is spoken of as *dialysis*.

Dialysis was applied to the preparation of various colloids. The mixed solution obtained by pouring silicate of soda into water acidulated with hydrochloric acid, was placed upon a parchment paper dialyser and allowed

to diffuse into water, the latter being occasionally changed. After the lapse of five days, seven-eighths of the original silicic acid was found to remain liquid upon the septum, and to be so free from hydrochloric acid and chloride of sodium as not to give a precipitate with acid nitrate of silver. The true hydrated alumina, and also Mr. Crum's metalumina, were obtained soluble by dialysing solutions of these oxides in the chloride and acetate of the same metal. So also the hydrated peroxide of iron, in addition to the hydrated metaperoxide of iron of M. Péan de Saint-Gilles, and the soluble hydrated chromic oxide. The varieties of Prussian blue are obtained soluble by dialysing their solution in oxalate of ammonia, the latter salt diffusing away. Stannic and titanous acids appear as insoluble gelatinous hydrates.

A solution of gum arabic (gummate of lime), dialysed after an addition of hydrochloric acid, gave at once the pure gummic acid of Frémy. Soluble albumen is obtained in a state of purity by dialysing that substance with an addition of acetic acid.

Caramel of sugar, purified by repeated precipitation by alcohol and afterwards by dialysis, contains more carbon than any of the caramellic bodies of Gélis; it forms a tremulous jelly when concentrated, and appears decidedly colloidal. Caramel, like all other colloids, has a soluble and an insoluble modification. The latter has its solubility restored by the action of alkali followed by that of acetic acid and subsequent dialysis.

Dialysis proves highly useful in separating arsenious acid and metallic poisons from organic fluids. Defibrinated blood, milk, and other organic fluids charged with a few milligrammes of arsenious acid, and placed upon the dialyser were found to impart the greater proportion of the arsenious acid to the external water in the course of twenty-four hours. The diffusate was so free from organic matter, that the metal could be readily precipitated by sulphuretted hydrogen, and the quantity weighed.

Ice, at or near its melting point, appears to be a colloidal substance, and exhibits a resemblance to a firm jelly in elasticity, the tendency to rend, and to redintegrate on contact.

The consideration of the properties of gelatinous colloids appears to show that osmose is principally an affair of the dehydration of the gelatinous septum under influences having a catalytic character, and that the phenomenon is independent of diffusion. The colloidal septum is capable of hydrating itself to a higher degree in contact with pure water than in contact with a saline solution. Colloidal septa, swollen in consequence of contact with dilute acid or alkali, appear to acquire increased sensibility to osmose, in consequence of their unusually high degree of hydration.

On Didymium, Lanthanum, Cerite, and Lanthano Cerite, by R. HEMMANN.

(Continued from page 73.)

Sulphide of Didymium is formed by heating the oxide in the vapour of bisulphide of carbon. It is a light, greenish-brown powder, evolving sulphuretted hydrogen with dilute acids, and, when heated, smouldering to a mixture of oxide and basic sulphate.

Oxy-sulphide of Didymium is obtained by fusing oxide of didymium and sulphide of sodium. When the mass is treated with water, Di_2OS remains as a gray residue, which dissolves in hydrochloric acid with evolution of HS .

Hydrated Oxide of Didymium.—Solutions of didymium salts give, with hydrate of potassium or sodium, a slimy, transparent, bluish rose coloured precipitate, which dries up to flesh-red pieces of hydrated oxide of didymium, which, however, cannot be obtained by this process free from carbonic acid. Ammonia throws down from solutions of didymium basic salts, which also appear as bulky, transparent precipitates, of a bluish-rose colour.

Chloride of Didymium.—If a solution of the oxide in hydrochloric acid be mixed with a sufficient quantity of sal ammoniac, a double salt is produced, which may be evaporated to dryness without decomposition. If this double salt be heated in a covered platinum crucible to redness, the sal ammoniac passes off, and chloride of didymium remains behind. It forms a rose-red mass, of radiated crystalline structure, and consists of DiCl :—

Di	57.205	1.	593.50	57.24
Cl	42.795	1.	443.28	42.76
	100.000		1036.78	100.00

When chloride of didymium, thus prepared, is dissolved in water, some oxychloride of didymium usually remains behind, in the form of rosy-red, pearly scales. Chloride of didymium deliquesces in moist air, and dissolves easily in alcohol.

Hydrated Chloride of Didymium.—Oxide and peroxide of didymium dissolve easily in hydrochloric acid, forming a rose-coloured fluid, which, when evaporated to a syrupy consistence, solidifies to a granular mass of crystals. According to Marignac, these crystals are monoklinœdric, and consist of the combination $\infty \text{P.OP}$ ($\text{P} \infty$). $\infty \text{P } 78^\circ$; $\text{OP} : \infty \text{P } 92^\circ$; ($\text{P} \infty$) : ($\text{P} \infty$) on $\text{OP } 67^\circ$. The composition is $\text{DiCl} + 4\text{HO}$.

Oxychloride of Didymium.—When hydrated chloride of didymium is heated, there passes off, besides water, much hydrochloric acid. There is thus formed the oxychloride as a white powder, insoluble in water and slowly and with difficulty soluble in hydrochloric acid.

Double Chloride of Didymium and Mercury. obtained by evaporating the chlorides of didymium and mercury, forms rose-red cubes. It is easily soluble in water, but not deliquescent. Its composition is $\text{DiCl} + 3\text{HgCl} + 8\text{HO}$ (Marignac).

Bromate of Didymium forms light, rose-red, permanent hexagonal prisms. Combination : $\infty \text{P.P.P}$; $\text{P } 147^\circ 58'$ (terminal edges), 67° (lateral edges). Composition, $\text{DiO.BrO}_3 + 6\text{HO}$.

Fluoride of Didymium.—Fluoride of sodium produces a precipitate in solutions of didymium salts, only slightly soluble in hydrochloric acid.

Carbonate of Didymium, obtained by precipitating didymium salts with bicarbonate of ammonia forms a light rose-red, which, when dried *in vacuo*, consists of $\text{DiOCO}_2 + 2\text{HO}$. Dried at 100° , it has the composition $2\text{DiOCO}_2 + \text{HO}$ (Marignac).

Nitrate of Didymium.—Oxide and peroxide of didymium dissolve easily in nitric acid, forming a rose-red liquid. By evaporation, the syrupy solution acquires an amethystine colour, and solidifies, after standing some time over sulphuric acid, to a crystalline mass, which deliquesces in moist air and dissolves easily in alcohol. When heated in the air it is converted into peroxide of didymium.

Arsenate of Didymium.—Arsenic acid gives with didymium salts a pulverulent precipitate only when

boiled. Arseniate of potassium, on the contrary, produces, even in the cold, a slimy precipitate. Both precipitates, when dried *in vacuo*, consist of 3DiO , 2AsO_5 , $+ 2\text{HO}$ (Marignac).

Phosphate of Didymium, $3\text{DiO}_2\text{PO}_5 + 5\text{HO}$. If a cold solution of sulphate of didymium be mixed with its equivalent of phosphoric acid,—viz., one atom phosphoric acid to three atoms oxide of didymium, two-thirds of the didymium are thrown down as phosphate of didymium, while one-third remains dissolved in the free acid. The phosphate of didymium so prepared forms a flocculent precipitate, which, dried at the temperature of the air, possesses the above composition. We obtain in fact,—

DiO . . .	53.88	3 =	208.5	53.82
PO ₅ . . .	46.12	2 =	178.6	46.18
	100.00		386.1	100.00
3DiO, 2PO ₅	87.19	1 =	386.1	87.30
HO . . .	12.81	5 =	562.5	12.70
	100.00		4427.6	100.00

The phosphate of didymium which remains dissolved in the free acid is thrown down by ammonia as a transparent, pasty precipitate, which dries up at the temperature of the room to transparent pieces of a beautiful rose-red colour, and with conchoidal fracture. By precipitating a hot solution of sulphate of didymium with phosphoric acid, Marignac obtained a pulverulent, white phosphate of didymium, of the composition 3DiO , PO_5 , $+ 2\text{HO}$.

Sulphite of Didymium, $\text{DiOSO}_3 + 2\text{HO}$ (dry) (Marignac). Oxide of didymium dissolves in aqueous sulphurous acid, forming a rose-red liquid, from which, on the application of heat, a voluminous precipitate separates, but which dissolves again on cooling, when the fluid still contains an excess of sulphurous acid.

Basic Sulphate of Didymium, obtained by precipitating sulphate of didymium with excess of ammonia, forms a light-bluish, rose-red, transparent precipitate, which dries up at the temperature of the air to pieces, with an earthy fracture and a rose-red colour, $3\text{DiO} + \text{SO}_3 + 8\text{HO}$.

Sulphate of Didymium.—Oxide and peroxide of didymium dissolve easily in sulphuric acid, forming a rose-red liquid. By evaporation, whether spontaneously or by the aid of heat, it forms dark, rose-red, granular crystals of hydrated sulphate of didymium. According to Marignac, the form of these crystals is monoklinœdric. The composition of this salt was found to be the same by the author as that determined by Marignac. It expresses, in fact, the unusual formula $3(\text{DiOSO}_3) + 8\text{HO}$.

Oxalate of Didymium.—Oxalic acid and oxalate of ammonia produce in solutions of didymium salts at first a caseous precipitate, which, however, soon sinks together to a crystalline, light, rose-red powder. Dried at 15° , the compound consists of $\text{DiOC}_2\text{O}_3 + 4\text{HO}$. Dried at 100° , it consists of $\text{DiOC}_2\text{O}_3 + \text{HO}$.

(To be continued.)

On the Production of the Ethyl Bases,¹ by M. CAREY LEA, Philadelphia.

I MENTIONED in a former number of this Journal that while engaged in the examination of the action of am-

¹ American Journal of Science and Arts.

ammonia on certain oxy-ethers, I had met with the experiments of Juncadella and De Clermont, and finding that the production of ethylamine by these reactions had been already indicated, I discontinued my investigations. Subsequently, however, having occasion to prepare a considerable quantity of ethylamine for other examinations, I determined to ascertain whether the action of nitrate of ethyl on ammonia could not be made use of as a convenient process. Juncadella had already proposed to mix nitrate of ethyl with three or four parts of alcohol, saturate the mixture with dry ammoniacal gas, and heat for two days to 212° in the water bath. This was a rather troublesome process, and a few experiments led me to the following very simple method, which I publish as having given me satisfactory results.

Nitrate of ethyl is mixed with an equal volume of strong alcohol. To this mixture is added a quantity of ordinary strong liquid ammonia, equal in bulk to that of the mixture. The nitrate of ethyl is thereby precipitated, but is nevertheless easily acted upon by the ammoniacal liquid. Three hours in the water-bath at 212° is generally sufficient to complete the reaction. As the process goes on, the nitrate of ethyl becomes brownish, gradually diminishes, and finally disappears. The resulting solution does not contain salts of ammonia and ethylamine only, as has been stated, but a large quantity of diethylamine and triethylamine.

As the nitrate of ethyl can be prepared in large quantity with great facility by a modification of M. Millon's process, I am inclined to think that this process will be found valuable for the preparation of the ethyl bases. It is necessary that the tubes should be strong, and not more than two-thirds full. Bottles hermetically sealed are not to be recommended unless extremely strong. In one experiment I operated with four eight-ounce bottles, all of which stood the test, but on repeating the process three of the four exploded at once, and the fourth subsequently.

The presence of alcohol is far from being essential. Nitrate of ethyl is readily decomposed at 212° by aqueous ammonia, and if the ammonia is in considerable excess, the decomposition is complete in three hours. If the excess is only slight, the time required for decomposition is greatly increased. In one experiment where 29 parts of nitrate of ethyl were heated with 57 of liquid ammonia, the decomposition was not complete till at the end of 15 hours. The use of alcohol, and the proportions above given, are what was found to give the most satisfactory result.

TECHNICAL CHEMISTRY.

On the Origin and Progress of the Phosphorus and Match Manufactures, by G. GORE.

(Continued from page 79.)

THE latest improvement of note in the manufacture of matches is that of M. Lundstrom, of Jonkoping, in Sweden. It consists in dividing the ingredients of the match mixture into two separate compositions, one being placed upon the ends of the splints as usual, and the other, which contains the phosphorus, being spread in a thin layer upon the end or lid of the box. The patentee uses the following mixture for the splints:—

Chlorate of potash	6 parts.
Sulphide of antimony	2 to 3 "
Glue	1 "

and the following for the friction surface, which has been previously made rough by a coating of glue and sand:—

Amorphous phosphorus	10 parts.
Sulphide of antimony, or peroxide of manganese	8 "
Glue	3 to 6 "

By this method the danger of fires arising from ignition of the matches by friction is avoided (because the matches will ignite by rubbing upon no other surface besides the prepared one); and that of poisoning is totally prevented by using the red or innocuous variety of phosphorus.

There is scarcely any manufacture of which the statistics appear more fabulous than that of match-making. To begin with England, in which the manufacture is comparatively small. The firm of Messrs. Dixon, Newton Heath, employ about 300 workpeople on the premises, and upwards of 100 at their own homes. Their stock of timber is generally of the value of about 8000*l.* or 10,000*l.* They consume 1 ton of sulphur per week, in the sulphuring of splints; and in twelve months they use between 4 and 5 tons of chlorate of potash, and 12 tons of glue. They produce about 43,000,000 of matches every week, or 2,160,000,000 matches yearly; reckoning the length of a match at $2\frac{1}{2}$ inches, the total length of these would far exceed the circumference of the earth. In London a single saw-mill cuts up 400 large timbers annually to make splints for matches. It has been estimated that from 12,000 to 15,000 gross of boxes of matches are produced weekly in London, indicating a production of 5,000,000,000 of matches yearly in that city. And another calculation has been made that the whole length of waxed cotton wicks consumed by one London manufacturer in the production of "Vestas" would be sufficient to reach from England to America and back again. One pound of phosphorus is sufficient for tipping 1,000,000 of German matches, or for 600,000 English ones.

The yearly consumption of phosphorus in the manufacture of matches in this country has been estimated at 6 tons, which, at a price of 2*s.* 6*d.* a pound, amounts to a value of 1680*l.*; and of chlorate of potash, 26 tons. A single merchant of London imports 8000 cwt. of cases of matches yearly. In 1854, 20,000*l.* worth of matches came into this country from the city of Hamburgh alone. We import at the present time at least 1500 tons of matches a-year from Sweden only. It has been estimated that 60,000*l.* worth of matches are imported yearly into Great Britain,—equal to 200,000,000 of matches daily; and that our daily consumption approaches the enormous number of 250,000,000, or more than 8 matches each day for every individual in the kingdom. In Belgium, the consumption of matches has been calculated to be 9 matches per day for every living person.

In France, the manufacture of matches is very extensive. Paris alone employs 1000 operatives, and produces 990,000,000 of boxes, worth in total 7200*l.* yearly. In Sweden there are 6 or more manufactories of matches; in one of them, in 1848, there was employed about 400 workpeople, and produced between 8,000,000 and 10,000,000 of matches daily.

But the greatest seat of match-making is located in Austria, where there are numerous manufactories which produce many millions per day of phosphorus matches: for instance, those of M. Pollak, at Vienna, and M. Fürth, in Bohemia, consume together about 20 tons of phosphorus annually, and give employment to about

6000 persons; and as one pound of phosphorus suffices for upwards of 1,000,000 of their matches, those two makers alone produce the amazing number of 44,800,000,000 of matches yearly. In the year 1849, there was exported from the port of Trieste alone nearly 200 tons of lucifer matches, and the whole produce of matches in Austria in that year was estimated at 2500 tons.

The cost at which both boxes and matches are produced is equally startling. M. Fürth "sells his cheapest boxes at one penny per dozen, each box containing 80 matches." Peter Harrass, of Suhl, in Prussia, sells his plain boxes at twopence per 100, and 1400 splints for one farthing. And De Majo, of Moravia, "sells a case of 50 boxes, each containing 100 lucifers, for fourpence."

Notwithstanding the great and universal advantages conferred upon mankind by the introduction of phosphorus into the manufacture of matches, it is not without some serious drawbacks. It produces a most painful disease, which attacks the jaw-bones of the workpeople, and causes them to decay, until, in some cases, they are entirely destroyed. This disease only attacks the operatives who are exposed to vapours arising from the match composition,—chiefly those who dip the splints, also those who are occupied in drying, cutting, and boxing the dipped matches. The workmen employed in other parts of the manufacture are wholly unaffected. The disease has been fearful in Germany and France, where so much phosphorus is used in the match composition, so much so as to excite the attention of the Governments of those countries; but it has not appeared to so great an extent here. It may be considerably, if not entirely prevented, by particular attention to cleanliness and ventilation, which has been already proved in the establishment of Mr. Hynam, of London; the most effectual remedy, however, would consist in the use of amorphous phosphorus instead of the ordinary variety. It is to be remarked, that in the manufacture of the phosphorus itself, the experience of many years has shown an almost complete immunity from any symptom of the disease; this may be partly attributed to the fact that the substance is kept covered with water from its first production to the vessels in which it is finally packed for sale.

Another great disadvantage is, that ordinary phosphorus is highly poisonous, and several instances are upon record where children have been killed through sucking the composition from the ends of matches. It might be also used for intentional poisoning, especially as phosphorus exists naturally to a large amount in the tissues of the human body; and phosphorus introduced into the stomach becomes gradually converted into phosphoric acid, which cannot readily be distinguished from that naturally present. The amorphous variety could not produce poisoning either by accident or intention, for Dr. De Vry, of Rotterdam, has administered it in various doses to animals without producing any ill effects.

Conflagrations have also frequently resulted from ordinary phosphorus matches, which could not possibly have occurred with the matches made with amorphous phosphorus under the patent of M. Lundstrom, already mentioned. In the records of fire insurance, we find that calamitous fires have been produced by cats knocking down boxes of matches, and by rats gnawing the ends of matches.

Let us endeavour to draw a useful lesson from the facts we have recorded,—not to despise or think lightly of the abstract facts or "small beginnings" of philoso-

phers, but rather to foster them, with a hope that, sooner or later, they may become of value to ourselves or our successors. Who would have thought that the curious, stinking, unctuous, luminous wax of Master Brandt would ever have become so important and universal an agent of civilization? That great modern innovator, the scientific faculty of man, has, by the certain process of experiment and induction, so immensely improved the means of producing phosphorus, and so marvellously adapted its properties to the uses and requirements of domestic and general life, that it has extended the civilising and ameliorating influence of the lucifer match to the uttermost ends of the earth. The matches of London, Manchester, and Vienna, are to be seen in the wigwam of the far-west Indian, the bush dwelling of the Australian, the habitation of the Mussulman, the frozen hut of the Greenlander, the hovel of the peasant, and the palace of the Emperor. Everywhere, as commerce extends its boundaries into newly-discovered regions, it is one of the first articles of civilisation which is introduced.

On the Preparation of Rosolic Acid and of Rosolates,
by M. JOUÏN.

M. RUNGE, in 1834, having remarked that in certain portions of a gas-making apparatus, the lime found therein became red, endeavoured to separate this coloured matter, and gave to it the name of rosolic acid, but without having well defined it.

In 1854, Mr. McDougall, a Manchester manufacturer, having observed that the lime used in the preparation of disinfecting coal-tar became, after a certain time, more or less red, took some of this substance to Dr. Smith, a chemist in the same town. After more attentive study than M. Runge had bestowed upon it, Dr. Smith succeeded in separating from it a solid brown substance, becoming yellow when dissolved in alcohol, and red on the addition to it of an alkali or of lime. He retained the name of rosolic acid given by Runge, for the first of these bodies, the red colouring matter being then considered as a rosolate.

Wishing to obtain a certain quantity of this acid for analyses, Dr. Smith sought for the most expeditious method,—the process for separating rosolate of lime being not only tedious but yielding small results; for the red lime mentioned contains only a few grammes of rosolate to several kilogrammes of the staple matter.

Supposing that rosolic acid was a modification of phenic acid, existing in the products used for the preparation of coal-tar, Dr. Smith passed phenic acid in vapour over lime in a red-hot tube, and found that the lime became red-hot only after a certain time, and he obtained only a small quantity of rosolate of lime. Then he tried the following process, which he ultimately preferred, as being the most simple. He heated a mixture of phenic acid, soda, and peroxide of manganese, and again obtained, and in larger quantities, the red matter, rosolate of soda.

Thus the question rested, when, having occasion to study phenic acid, I indirectly found Dr. Smith's rosolic acid, without then being aware of his researches; and I found that rosolic acid and rosolates could be much more easily obtained if, in the process given by the Manchester chemist, peroxide of mercury were substituted for peroxide of manganese.

In short, with manganese are obtained, besides rosolate of soda, manganates of soda, which decompose when

it is attempted to separate them for the purpose of purifying the colouring matter, forming oxides of manganese which must be separated, and thus necessitating a lengthened purification, while if oxide of mercury is substituted for the oxide of manganese in the mixture of carbolic acid and soda, we very rapidly obtain (ten minutes suffices), and at a temperature below 150° , the transformation of carbolic into rosolic acid, and the formation of a rosolate of soda of a beautiful red. This salt then appears as an excessively viscous liquid, solidifying almost entirely when cooled, and simply needing decanting to purify it, which frees it from the reduced mercury which remains at the bottom of the vessel.

This colouring matter, obtainable of various tints according to the quantity of oxidising matter employed, has not yet been used for dyeing, on account of its instability under the action of acids, which by neutralising the alkali gives to rosolic acid its arnoffo colour; but I trust that trials now in operation will result in utilising it for dyeing.

A fact, which I re-mention here, relating to phenic acid, is, that if heated with bichloride of mercury this acid will also yield rosolic acid, at the same time producing hydrochloric acid; and, with a distilling apparatus, rosolic acid can be collected in the retort, while the excess of phenic acid, saturated with hydrochloric acid, condenses in the receiver and fuming excessively in the air.

Rosolic acid proceeds from oxidised carbolic acid; for if the latter is represented by the formula $C_{12}H_6O_2$, that of the former becomes $C_{24}H_{12}O_6$. This formula is given as the result of three analyses.

On Certain Copper and Zinc Alloys, by M. E. KOPP.

AN alloy, patented by M. Gedge (*Dingl. Polyt. Journ.*, vol. clviii. p. 273), remarkable for its malleability—for when hot it can be forged, stamped, rolled, and drawn with the greatest ease—gives, on analysis, the following numbers:—

Copper	.	.	.	60.00
Zinc	.	.	.	38.15
Iron	.	.	.	1.50
				99.65

The proportion of zinc can be increased to 44 per cent. This alloy, which is recommended for sheathing vessels, seems identical with Aich's alloy (*Technologiste*, May, 1861, p. 429), to which the following composition is assigned:—

Copper	.	.	.	60.00
Zinc	.	.	.	38.20
Iron	.	.	.	1.80
				100.00

The colour of this alloy is rather darker than brass; its fracture is paler, bending at a red heat, and of fine grain. It takes a high polish. Its density is 8.37 when annealed, and when hardened 8.40. It is extremely ductile, though not so flexible as brass. Experiments made in the Austrian marine arsenals show that the Aich's metal possesses a high degree of tenacity; that it maintains its properties at red heat, provided the temperature is not raised to a clear red heat; that it can be puddled, hammered, and worked like the best forged iron; that when cold it can be considerably bent without cracking or breaking; that its absolute and relative resistance approximates to that of iron of good quality.

It is very probable that these alloys are nothing more than malleable brass or Chantz metal, concerning which M. Storer published a most interesting paper in the *Repertoire de Chimie Appl.*, 1860, p. 213. It is very likely that the iron is useful only in diminishing the nett cost of these alloys.—*Repertoire de Chimie*.

On the Manufacture of Iron,¹ by E. RILEY, F.C.S., late of the Dowlais Iron Works.

THE author commenced by stating that, having considered the various ores and coals used in the manufacture of iron and the working of the blast-furnace, he should proceed to the pig iron, and the different processes it underwent in its conversion into merchant bars and rails.

The various qualities of pig iron were considered: they were known in commerce by the Nos. 1 to 6, Nos. 1 to 3 being foundry iron, and Nos. 4 to 6 grey forge iron; besides these there was also mottled and white pig. No. 1 iron was only produced when the furnace was in the best working order, and required a heavy burden of coal and limestone; it was, consequently, the most expensive iron to produce; any little irregularity in the blast furnace soon reduced the iron to the lower numbers, at the same time altering the cinder, which was very grey when No. 1 iron was produced.

On referring to the analysis of various qualities of pig iron (from Nos. 1 to 6) it will be seen that the percentage of silicium is directly as the quality of the pig, being the highest in No. 1, and lowest in No. 6; whereas the sulphur is inversely as the quality of the pig, being the lowest in No. 1, and highest in No. 6. The phosphorus is a constant quantity. The samples of pig analysed were made from the same materials. The carbon does not differ very materially in quantity in the grey iron, but as you get on to mottled and white the carbon then becomes either partially or wholly combined with the iron, whereas in very grey iron the carbon all exists as graphite.

When the sulphur is present to any extent in an iron ore it is difficult to obtain grey iron, and when it is in large quantity it becomes almost impossible, unless it be mixed largely with other ores, the effect of sulphur on grey iron being to liberate the carbon and reduce the quality of the iron. Experimentally, if sulphide of iron be mixed with grey iron, graphite is separated, and if the sulphide of iron is used in any quantity the iron becomes white; thus it is that finery and forge cinders always make, when used alone, a white iron, from the high per-centage of sulphide of iron they contain.

In considering the quality of grey pig iron for foundry purposes, it must be admitted that the chemical composition of the pig is not necessarily an indication of its strength; and it is always necessary that its physical condition should be considered, although, as a rule, which generally holds good, you will find that pig iron which contains a high per-centage of silicon is weak, and more especially so when, besides this silicon, the iron contains a high per-centage of phosphorus, which is generally the case in iron made from the oolitic ores. The sulphur cannot be present to any extent in very grey iron; it never exceeds, and is generally below, .05 per cent. in No. 1 and No. 2 foundry pig. Pig iron, after being re-melted, is generally increased in strength. This is due more to an alteration in its physical condition than

¹ Abstract of a Paper read before the Society of Engineers.

to any chemical change, and is probably due to the iron becoming more homogeneous and uniform throughout. It has been found practically that a very siliceous iron, by being re-melted, was greatly increased in strength, without in any way altering its chemical composition.

It would naturally be asked, has the chemical composition of pig anything to do with its strength, and is not its physical condition the main point? The author considered that the chemical composition was of great importance; at the same time, he admitted that the composition of pig iron was not well understood, more especially as to the way in which the various elements existed and were combined. He also thought that some elements existing in pig had hitherto not been detected; he had himself, in several instances, detected titanium, which, he believed, had not been found before. Again, the elements in pig iron—more especially carbon and silicon—were capable of existing in very different states, known to chemists as allotropic conditions (or the same element existing in a different physical state, and not unfrequently playing a different part in combination). Thus, we have carbon as the diamond, graphite, and charcoal; and we have yet to learn, not only in what condition the two elements above-named exist in various qualities of iron, but also, from the great similarity in many of the properties of them, whether they may not, in fact, replace, to some extent, each other; and thus, possibly, you may have silicon playing the part, and, in fact, become equivalent to, carbon in certain cases.

It has recently been shown, by Professor Brodie, that carbon has, or ought to have, three different atomic weights, and you may have carbon existing in its three states in the various qualities of pig, altering it physically, and differing only chemically, in the aggregation of its atoms, the actual amount of carbon being identical.

Undoubtedly as our knowledge and experience increases we shall be able to give more satisfactory reasons than we can at present, as we are only able to draw general conclusions, which, I believe, as a rule are correct.

Pig iron from various localities was then considered, the Welsh being generally noted for its strength. It was not so fluid as the Scotch and Staffordshire, which was more adapted for light castings. The general effect of silicon and phosphorus was to make iron more fluid, but to diminish its strength. The hot blast iron was also considered more adapted for some castings than others.

Various processes were noticed for toughening pig iron, which generally consisted in reducing the impurities by a process of refining or oxidation, or mixing wrought iron or metal with the pig.

The treatment of the pig in the refinery and the construction of the latter, were next considered. Formerly the pigs were re-melted in the finery, but in many works the iron was run direct from the blast-furnace into it. White pig was much more easily blown than grey pig; the former quality was generally used in Wales for rails and bars, and it is only when the very best quality of iron is made that grey pig is used.

The finery has, however, in many works been superseded, and the pig is taken directly to the forge and puddled. When pig is used in the forge, it is called boiling; when metal puddling, in some works it is still found advantageous to use the finery partially, and it is only when the pig is of good quality that it can be done away with altogether.

The author then referred to diagrams of the puddling-furnace, and noticed the great improvement that had

been effected by the use of cast-iron bottoms. They were generally one and a-half to two inches thick, and rested on bars so as to allow the air to keep them cool. In boiling pig, the action of the iron and cinder (which was much more fluid than in puddling) was very great on the sides or bushes of the furnace, and great difficulty was experienced in keeping them intact. Limestone had been found to stand better than anything else, although it made the iron red-hot, and was objectionable on this account. Red ore had been used, and a mixture of red ore, hammer slag, and lime with more or less success; also spathose iron ore had been found to stand very well, and in America steatite, or soapstone, had been used successfully. Some works had a mixture of their own, which was kept secret, but generally consisted of red ore hammer slag and lime, in various proportions. The maintenance of the bushes of the puddling-furnace was of great importance in an iron works. In Staffordshire, calcined tap cinder was used for the bottoms of puddling-furnaces.

The various qualities of pig, and their working in the forge, were next considered; in Wales, where white pig iron was used, there were two, perhaps three, varieties, which worked very differently in the forge. First, you have what is technically called "strong iron." This iron is more or less siliceous, and cast solid with a convex face when cast in sand or ashes; with a concave face, when cast in chills (cast iron moulds). It is very sonorous, and rings like a bell when struck, and breaks with a perfectly solid white and crystalline fracture. This is the best description of white forge iron, and will make bars or rails of excellent quality.

The next description of white forge iron is when the pig contains a high per-centage of sulphur and phosphorus; the iron is then thick, and runs into the chills or sand with a very rough face, covered with warty excrescences, strikes dead, like lead, when struck, is frequently not solid, and is of a dark white colour; this iron is known as "weak iron," and is always produced from finery and forge cinders, when they are used in any quantity on the blast-furnace.

When very siliceous iron ores are used, the tendency is to get a siliceous pig. Finery and forge cinders do not, as might be anticipated, make a siliceous iron, except when they have been calcined and rendered infusible.

In some cases you have pig iron siliceous, and weak at the same time, from the presence of sulphur and phosphorus. The pig is then of the worst possible kind.

Siliceous pig iron is much more difficult to refine or puddle than weak pig. The author mentioned a case where white pig iron, containing $3\frac{1}{2}$ per cent. of silicon, was blown for seven hours in a finery, and was not then metal; this pig, when puddled, worked to a yield of 27 cwt. of pig to a ton of puddled bar, and after two heats the men would not work any more. It was found in practice advantageous to mix the strong pig with the weak in the forge. The author considered that silicon, to a certain extent, in forged pig was advantageous. He found that the best white forged pig contained from 1 to $1\frac{1}{2}$ per cent.; also pig made wholly from Welsh mine contained the same amount. This per-centage of silicon gave what was known as strength to the iron, but when the silicon exceeded the above-named proportion, then the iron became difficult to work; the effect of the silicon was to retard the puddling process, and thus it gave time for the impurities to be more completely separated.

The skill of the puddler was of much importance, and the author warned all engineers not to rely on single

experiments made on the yield of pig iron. The only way to get at the true result was to take the working of a whole forge.

The average quantity of coal used to make a ton of puddle bar in Wales was 17 cwt., in some cases less, and the quantity of pig from 22 to 23 cwt.

The next point considered was the mechanical treatment of the iron. This the author considered a very important one, and quite irrespective of its chemical composition. In most works in Wales the squeezer is used, and in some works a patent squeezer, consisting of three grooved eccentric rollers. The latter was considered preferable to the former. The other mechanical means of compressing the iron were the old tilt hammer and the steam hammer. Formerly the old tilt hammer was the only means of compression used, but since inferior iron has been made by driving the furnaces and using impure ores, the iron would not stand the old tilt, and the squeezer was introduced, by the use of which almost anything can be shingled into a bloom and passed through the rolls, whereas, with the old tilt hammer, the iron from the first has to bear the full weight of the blow. This does not apply to the steam hammer, as with it the blow can be regulated to any nicety.

Lately, engineers, in their specifications, have stipulated that the iron shall be hammered and not squeezed, and the plan has been adopted of doubling the puddle balls by slightly hammering them, placing them one on the other, and welding them into a slab for the head of the rail; this makes the rail head crystalline, and not fibrous, as it is only once submitted to the drawing action of the rolls.

The iron, after squeezing or hammering, is passed through the rolls, and rolled into No. 1 iron or puddle bar, which is cut by shears into the requisite lengths for the subsequent pile.

The different methods of making the various piles for rails, &c., were entered into, the great object in piling being to get the pile as solid as possible and free from interstices. The piles were frequently made of puddle bar, of different widths, piled alternately so as to break the joints, and also, in some cases, the puddle bar was cut in short lengths equal to the width of the pile, and each layer piled at right angles to the previous one. This had a tendency to make the iron less fibrous.

The various sections of rails in use were then alluded to. The double-headed rail generally was made with slabs at the top and bottom of the rail. For the best quality of rails they were about two inches in thickness, and the rails were double heated. Some engineers had their rails made of three hammered slabs, one piled on the other.

(To be continued.)

A Course of Ten Lectures on Inorganic Chemistry, by Dr. EDWARD FRANKLAND, F.R.S., Lecturer on Chemistry at St. Bartholomew's Hospital.

LECTURE X.

It is now nearly a century ago since Scheele, the great German chemist, mixed binoxide of manganese with hydrochloric acid. He noticed that a gaseous body was disengaged possessing a greenish yellow colour, and

exhibiting very remarkable properties. He investigated it to a certain extent, and the discovery of this remarkable and new element soon attracted the attention of other chemists, especially of several chemists in France, who continued the investigation of the body. The substance was produced, as I have said, by the action of binoxide of manganese—a body, therefore, containing oxygen, and we may say oxygen in excess—upon hydrochloric acid—a compound which at that time was termed “muriatic acid,” sometimes, also, “marine acid,” as being an acid obtained from sea-salt. On account of this origin of the new substance which Scheele had discovered—namely, its origin in muriatic acid and an oxidising body like binoxide of manganese—it received the name of “oxymuriatic acid.” The chemists of that day thought it was produced by the union of oxygen with muriatic acid. This body being discovered about the time that Davy was beginning to prosecute his interesting chemical researches, very soon attracted his attention, and from experiments which he made upon this body discovered by Scheele he soon found that the view of it then held by chemists was perfectly untenable; that, in fact, it had as good a claim to be considered an elementary substance as oxygen, hydrogen, nitrogen, carbon, or other elements known at that time. He proposed for it the name “chlorine,” from a Greek word signifying greenish colour, that being the colour of the gas. Here is some of it in this vessel. This view of Davy, or, we should say, this fact, which Davy proved by experiment, that the body could not be decomposed—that constituting our definition of an element—was not generally received, and Davy's view of chlorine was for a long time contended against. I remember myself the time when it was not considered particularly unorthodox for chemists still to look upon this substance as an oxide of muriatic acid.

This element, chlorine, which is in many respects a very interesting counterpart of oxygen, although differing in other respects widely from that element, may be obtained by several processes, but may be best procured by the one to which I shall confine myself. This process consists, in fact, in the identical operation by which Scheele first prepared this gas. It consists in placing the binoxide of manganese, containing one equivalent of manganese and two equivalents of oxygen, in contact with hydrochloric acid which is prepared largely for manufacturing purposes, and which is therefore readily obtainable. The solution of that acid is the liquid which we have in this bottle. If we mix together these two substances and apply heat to them, this gas, chlorine, is evolved at once in large quantities; and the mode in which it is evolved, and which was first rendered clear by Davy, will be made evident to you by these cubes. Here is our muriatic or hydrochloric acid; we will take two atoms of it; we shall then consequently have two equivalents of hydrogen and two equivalents of chlorine. That is one of the substances. The other substance we use is the binoxide of manganese, containing one equivalent of the element manganese and two equivalents of oxygen. These bodies placed in contact with each other act in this way: the two equivalents of oxygen combined with the manganese take out from the hydrochloric acid the two equivalents of hydrogen contained in those two atoms of the acid. They come out, therefore, thus [pairing off the cubes representing the hydrogen with the cubes representing the oxygen]. There is one atom of the new compound,—there is the other. Now, what is this that we bring out? Hydrogen and oxygen in equal proportions—equal equivalents: this is, obviously, water. We thus have two equivalents of water separated by this reaction; and one equivalent of manganese and two equivalents of chlorine are left. These two equivalents of chlorine cannot remain combined with the manganese, if the temperature be slightly elevated, that is to about 80 or 90 degrees Fah.; and the result

of the decomposition which may be regarded as taking place simultaneously with the separation of these two atoms of water is, that one of the equivalents of chlorine combines with one equivalent of manganese, forming the metallic salt, chloride of manganese, which remains dissolved in the water; and then we have one equivalent of free chlorine left. This was the re-action which Davy demonstrated to take place in this process of mixing hydrochloric acid with binoxide of manganese, and exposing the mixture to a gentle heat.

Now, this element—chlorine—is remarkable, in the first place, for the great intensity of its affinities. It is difficult to say whether oxygen or chlorine possesses the most powerful affinity for other substances. There is a sort of contention for the mastery between these two elements. Sometimes we have chlorine expelling oxygen, from its combinations, and we have sometimes oxygen expelling chlorine. We may say that the affinities of the two bodies are very nearly equal, but there is just this peculiarity about chlorine, that its affinities are generally capable of being exerted at ordinary temperatures. We have found that oxygen requires usually the application of an elevated temperature to bring its affinities into play. When we wish oxygen to combine with hydrogen, for instance, we have to apply heat to the mixture in order to bring about that combination; but chlorine, on the other hand, is capable, in a great majority of cases, of combining with other substances at ordinary temperatures.

On account, first of all, of its very powerful affinities, and, secondly, of its property of combining with other bodies at ordinary temperatures, chlorine never exists free in Nature; we never can find a trace of chlorine in a free state naturally. It exists, in fact, almost entirely in one form of combination, namely, in this form—a form in which all of us know it very well—as common salt, or chloride of sodium, of which this is a native specimen [exhibiting a piece of rock salt]. The great bulk of this material exists chiefly, as you are aware, in the waters of the ocean. Considerable portions of it have, however, been deposited in the bowels of the earth by the evaporation of inland seas, possibly, or by some other geological process. We make borings, and send down water which absorbs the salt, then pump up the solution and evaporate it, and thus we obtain our supply of chloride of sodium. This natural compound of chlorine contains one equivalent of sodium and one of chlorine. In addition to this compound, we meet with it, though in much smaller quantities, united with potassium, with calcium, with mercury, and occasionally, though very rarely, with silver. The three chief compounds of chlorine which we meet with are those with sodium, potassium, and calcium; and if you look towards our list of elements you will find that these bodies belong to the metals, or to the most positive of our positive elements, whilst chlorine is one of the most negative of our negative elements. The consequence is, that the chlorine which exists in this chloride of sodium is retained there by a very strong affinity, and this metal most effectually neutralises the negative energy of the chlorine. I will not prepare any of this gas before you, because its preparation is always attended with the escape of some of it into the room, and being an exceedingly irritating gas, it would be very unpleasant to prepare it here. I have, however, several jars of it already prepared, and in collecting it it is necessary either to receive it over warm water, or to collect it by the process of displacement. We cannot collect it over mercury, because it immediately combines with the mercury at ordinary temperatures. There again you see it differs from oxygen, which does not combine with mercury at ordinary temperatures. Cold water also absorbs from two to three times its own volume of this gas, and, therefore, there is a considerable loss if we collect it over cold water.

Chlorine possesses the following properties:—In addition to the colour, to which I have already directed your atten-

tion, it has a powerful and exceedingly irritating odour. I dare say most of you know this odour. It is the odour that you perceive to issue from that disinfecting substance called chloride of lime, when it is exposed to the air. In that case you have it in a very mild form indeed. The quantity which is given out to the air from the chloride of lime is very slight, but if you attempt to inhale it in the concentrated form, the irritation to the air-passages of the lungs is perfectly unbearable, and in a concentrated form a couple of cubic inches is quite sufficient to deprive a man of life, if it gain access in its undiluted form to his lungs. The specific gravity of this gas is about two and a-half times that of the atmosphere, and therefore we can collect it in such tall vessels as these without much difficulty. It is one of the gases, also capable of being liquified. It requires the pressure of only four atmospheres to liquify it, and then it condenses into a yellowish, mobile liquid, the properties of which were first investigated by Mr. Faraday. It is, as I have said, distinguished for its intense negative energy, and for its power of combining with positive elements with great energy. But it is very peculiar—in its taste, I was almost going to say—but at all events in its selection of elements to combine with, it differs considerably from oxygen.

In the first place, as we have already noticed, its affinities are capable of being exerted at ordinary temperatures. Here we have a jar of it, and into this jar I will dust a little powdered metal, and in order that you may not be annoyed with the odour of the gas more than can possibly be avoided, we will perform the experiment under the ventilator. Here I have in this little gauze bag some metallic antimony, reduced to a fine powder, and when we shake it over the mouth of the jar, and cause the powdered metal to fall into the chlorine, you see, the moment it comes in contact with the gas, it ignites, and the two combine, forming chloride of antimony. We may repeat this experiment with powdered arsenic, and several other metals. We may also ignite sodium or potassium in this gas, for those metals are capable of burning in chlorine with very great brilliancy; but I think we had better dispense with any further experiments of this sort, as they might give us too large a quantity of chlorine in the atmosphere. Some of the non-metallic positive bodies—phosphorus, for instance—are also peculiar for possessing powerful affinities for chlorine, and if we introduce a piece of phosphorus into a jar of this chlorine gas, it at once takes fire, and continues its combustion. It is not necessary to ignite it before introducing it into the gas, as in the case of oxygen.

In making this experiment with phosphorus, I wish you also to notice some facts with regard to the light of the combustion, for it is a very instructive experiment. In burning in chlorine gas, phosphorus produces a volatile substance, the chloride of phosphorus, furnishing no solid particles from which the light can radiate, as it does in ordinary gas flames, or flames generally luminous. Now, I will first plunge the phosphorus into the jar of chlorine; it will ignite spontaneously, and you will see that it will burn with a very dim light, scarcely perceptible, I should imagine, at a distance. I will then bring the phosphorus out into the atmosphere, and then it will burn at the expense of oxygen, and form a solid, non-volatile body—phosphoric acid and the phosphorus on emerging from the chlorine, will emit a very considerable amount of light. But the amount of light thus emitted, depends very much upon the temperature of the combustion, and, therefore, if we transfer our phosphorus from the atmosphere into a jar of oxygen, we shall then see the difference of luminosity which occurs in that case simply by an increase in the temperature, because in the air we have the same product, namely, phosphoric acid formed in the same quantity; but in the jar of oxygen you have not the effect of atmospheric nitrogen to diminish the heat and consequently the light evolved by the flame.

There is our piece of phosphorus, and it at once ignites when it comes into the chlorine, and you see with what a very minute amount of light it burns there. Now, we will bring it into the air, and you see the very much greater luminous effect it produces here; and lastly we will plunge it into the oxygen, when the light becomes almost too intense for the eye to bear. The only difference between the combustion in air and in oxygen being the great elevation of temperature which takes place when combustion occurs in the latter.

Chlorine possesses some peculiarities in its tastes, so to speak, for combination. It unites with hydrogen and with the metals, with very great energy, but it is incapable of uniting directly with carbon. At any temperature to which we like to expose the two elements, they will not unite. Carbon, you will recollect, burns in oxygen at an elevated temperature with very great energy indeed, and we have some forms of carbon which take fire in atmospheric air without any application of heat whatever, but you cannot by any such direct process induce carbon to combine with chlorine.

This renders the action of chlorine on any ordinary combustible very peculiar. If we plunge a taper, for instance, into a jar of this gas, the taper will continue to burn for a few moments, but it is very soon extinguished. The taper at present burns with its ordinary luminous flame. Now we will plunge it into this jar of chlorine, and you see what an immense amount of smoke it produces, and how dimly it burns, and I think we shall find presently that it will be extinguished. It is now extinguished. It is incapable of continuing its combustion in the chlorine for this reason—the chlorine is only capable of uniting with the hydrogen of the combustible, and it separates the carbon of the wax taper. The smoke that was given off from the flame was due to the separation from the wick of the particles of carbon which are totally consumed while the taper is burning at the expense of oxygen. These particles of carbon gradually choke up the pores of the wick, and prevent the ascent of the wax to the summit of the wick where it would be consumed, and therefore the taper after a short time is extinguished. A gas light is capable of burning in chlorine for any length of time. It burns with a smoky flame, but it contains so much more hydrogen than the candle-flame, whilst it has no wick to become choked, that it is capable of continuing its combustion. There is another experiment illustrative of the same thing. Camphire is essentially a compound of hydrogen and carbon, like the wax of the taper, and if we spread it over a large surface of paper we see very strikingly the relative affinities of the chlorine for the hydrogen and for the carbon. We shall find, I think, if our turpentine is sufficiently pure, that it will be spontaneously ignited by the chlorine; the chlorine will attack the hydrogen of the turpentine, and the whole of the carbon will be deposited in a dense cloud of smoke as in the case of the combustion of the taper. I will pour a few drops of this camphire upon paper and then plunge it into this jar; you see we have it spontaneously ignited and the carbon separated from it as a dense fuliginous cloud, which in fact has covered the interior of the vessel with a mass of carbon, rendering it perfectly black. This is one of the peculiarities, then, of chlorine—its powerful affinity for hydrogen and its almost total want of affinity for carbon. It is true that we can get compounds of carbon and chlorine, but we can only get them by indirect means. This is effected by first combining carbon with some other element, and then removing that element by means of chlorine; we cannot make them unite directly in this process of combustion.

Another of the peculiarities of chlorine, serving to distinguish it from oxygen, is the effect of light upon its affinities; in fact light is to chlorine, in a great measure, what heat is to oxygen. We have seen that the application of heat to mixtures of oxygen with combustible

elements, as hydrogen, for instance, is capable of causing those elements to combine. In the same way the application of light in some cases to mixtures of chlorine with similar elements causes them to combine. I will endeavour to render this visible by an experiment which I intend to make here: it is an experiment which requires a good many precautions to make it succeed, and as I have not had an opportunity of trying it before the lecture, I cannot promise you success. What I am going to do is this,—I am going to mix together hydrogen with chlorine in one of our collodion balloons. These two gases are produced by the electrolysis of muriatic acid, which is torn asunder in the same way as water, and we have its two elements, chlorine and hydrogen, evolved in equal volumes. If we then connect our balloon here with the exit tube of this decomposing apparatus, we shall be able, I trust, in this way, to fill it with the mixed gases. [The collodion balloon was attached to the decomposing apparatus and the room was darkened.] We shall soon have filled that balloon with the mixed gases; and you see we are doing it with the exclusion of daylight, because that would cause the gases to ignite or combine, and defeat our experiment. We have here two parabolic reflectors—copper reflectors, silvered. We shall produce the electric light in the focus of the lower one, and as soon as our balloon gets near the upper one, the effect of the lower one will be to collect and gather up all the rays given off from the coal points which we shall here ignite, and to send them as a solid cylinder of rays, so to speak, against the upper reflector, and the upper reflector will receive this cylinder of rays, and will concentrate them to a point at some five or six inches lower than the level of the upper reflector; and thus we shall have our balloon exposed to this intense light so concentrated. We will just try our mirrors, and ascertain if we are likely to get a sufficient amount of light upon the balloon to effect the experiment. Whilst the balloon is filling, I will show you the corresponding experiment with the mixed oxygen and hydrogen gases which we will cause to explode by heat, just as we hope to make the mixed hydrogen and chlorine explode by light. For this purpose we will inflate another balloon with these mixed gases. [A collodion balloon similar to the one being inflated with the hydrogen and chlorine was attached to the vessel containing the mixed hydrogen and oxygen.] Now, you see, our second balloon is inflated, and I think it will possess a sufficient ascending power to reach the top of the theatre, and we will set light to it by means of a little bit of thread impregnated with nitre, which will act as a fuse; and when that fuse burns so as to come in contact with the collodion balloon, it will ignite the envelope, and will communicate a sufficient amount of heat to the mixed gases to cause the mixture to explode. [The balloon ascended to the top of the theatre, and a light having been previously applied to the thread, the latter burnt away until the fire reached the balloon and exploded the gases.] There, you see, is the result; the two gases ignite; and now I hope to produce a similar effect with the chlorine and the hydrogen by the agency of light. I think we may, perhaps, have a sufficient quantity here for our purpose. We will at once bring our balloon up to its proper position, and you will see the result. [The balloon was brought into focus, and immediately exploded.] You see, our two gases by the action of light produce just the same result as we produced in the other case by the action of heat; the moment the two coal-points were separated that concentrated light fell on the balloon, and produced this effect, which is not due to heat, as you see the envelope of the balloon is still unconsumed. Thus light is to chlorine to a certain extent what heat is to oxygen.

We have the same intense affinity of chlorine for hydrogen coming strikingly into play also in the processes of bleaching and disinfecting by chlorine, for chlorine is one

of our most powerful disinfectants. I will now endeavour to show you the mode of bleaching by means of this agent, chlorine. For this purpose we will use a solution of the gas. Here we have a cylinder full of a decoction of cochineal, which possesses intense colour. To this we will add some of the chlorine-water, and you see where it descends how the colour disappears. I do not know whether we have added quite sufficient, but probably we have enough to destroy the whole of the colour contained in that cylinder. You see the colour is gone under the action of the chlorine. Now, the action of the chlorine in destroying colour is the same as in the disinfection of noxious compounds. It consists in the removing, more or less completely—in the one case from the coloured compound, and in the other case from the noxious compounds which we wish to render innocuous—the hydrogen which those compounds contain. Let me try to illustrate this by some of our blocks. We will collect together here some atoms of chlorine; and here we will form a hypothetical miasmatic atom if you please which shall consist of nitrogen, carbon, hydrogen, and oxygen. This we may regard, then, as a hypothetical miasmatic atom, containing carbon, nitrogen, hydrogen, and oxygen. Such an atom is gradually undergoing oxidation; the hydrogen is gradually removed by atmospheric oxygen and replaced by the latter element. So long as this goes on, so long does this atom retain its noxious property. Before the process begins, it is innocuous; when it is completed, it is again innocuous. It is only while it is going on that noxious effects are to be apprehended. Now, the action of chlorine upon such a substance is to complete at once this process of removing the hydrogen from the atom. I will show the mode in which the hydrogen is removed. Two atoms of chlorine are required for the removal of each atom of hydrogen from this infectious matter. It is done in this way. One of these atoms of chlorine takes out an atom of hydrogen, brings it out in the form of hydrochloric acid, and the other atom of chlorine goes into the place of the hydrogen; so that you see now we have a body containing one equivalent less of hydrogen than we had before, and that hydrogen is replaced by chlorine. If this operation be repeated, we shall then remove the whole of the hydrogen from this noxious substance, and we shall then have replaced the whole of this by chlorine. The substance is no longer spontaneously oxidisable, and is deprived of its power of burning or slowly oxidising in atmospheric air. Its hydrogen is completely removed by the chlorine, and its noxious qualities are destroyed, it being no longer capable of undergoing oxidation, or of producing noxious effects.

The action of light upon chlorine, in producing compounds of that element, leads us naturally to speak, in the first place, of the action of light generally upon chemical affinity. This influence is far more restricted than the influence of heat upon the chemical force; nevertheless, the cases in which it occurs are of very great importance, and very considerable interest. For instance, that operation to which I alluded in the last Lecture,—the operation by which plants are capable of removing from the air carbonic acid thrown into the atmosphere by combustion and respiration, and returning to the air the oxygen contained in that carbonic acid,—can only take place in the presence of light; it cannot be carried on without luminous influence. This, then, is an instance of a grand modification of chemical affinity which is taking place all around us, and on which, in fact, life almost entirely depends. Of this process we may say we know simply nothing, for we have not the slightest idea how, by the action of light, the leaves of plants are capable of decomposing carbonic acid; we cannot imitate it in any of our processes; we can only effect it by the agency of our most powerful affinities. In addition to this grand operation of light in modifying chemical affinity, we have several others which are of considerable importance. We have this

effect upon the affinities of chlorine, bromine, iodine, and silver; these are the chief elements, in fact, on the affinities of which light is capable of exerting an influence; and if I may be permitted at all to generalise upon this influence, I should say that in the case of chlorine the affinities of that element are almost invariably increased by the action of light. The affinity of bromine is little affected; that of iodine and of silver is greatly depressed under the influence of light, so that a compound which iodine would be capable of forming in the dark it would not be capable of forming in the light; whilst a substance which chlorine would be incapable of forming in the dark it could produce under the influence of light. Now, the different rays of which white light is composed, do not all of them exercise this influence upon affinity, it is only one class, or one set, of those rays, the most refrangible of them, those that are capable of being most turned out of their course by passing from one medium to another, it is only these most refrangible rays that are capable of exerting this influence. I will endeavour to show you upon this screen the rays to which I refer, and we will endeavour then to get some chemical effect from those rays. [The room was darkened, and the prismatic spectrum thrown upon the screen.] There you have what is already well known to you, namely, the spectrum of the electric light—a beautiful series of colours, beginning at one extremity with red, then orange, then a band of yellow, then of green, then a band of blue, and finally, a band of indigo, but it is only the rays at this blue extremity of the spectrum that exert this chemical action; in fact, we may say that the rays at the other extremity rather neutralize what has been done by the rays at the blue extremity. These so-called "chemical rays," are invisible to the human eye; possibly, they cannot penetrate to the retina; at all events they are incapable of giving us the sensation of light when they reach it, supposing they do arrive there. Now, I will endeavour to make these rays visible to you by a process for which we are indebted to Professor Stokes. I have here a piece of uranium glass. You see this glass becomes luminous in the invisible rays of the spectrum beyond the blue. A piece of paper covered with sulphate of quinine will give us a somewhat similar result. That paper is illuminated in the dark portion of the spectrum, and these are the very rays which affect chemical affinity to the greatest extent. We will now interrupt this spectrum, or intercept it on its way to the screen by a photographic plate, by means of which, I think I shall be able to obtain an image of the spectrum, and to show you the way in which these rays modify chemical affinity. We will first get our image upon a sheet of ground glass, and in such a position as will enable us to receive it upon a glass plate prepared with collodion. There we have a tolerably sharp representation of the orange, the yellow, the green, the blue, and the indigo; and now the chemical effect will only begin at the line where you see the luminous spectrum ends, while the other or visible part will produce little or no chemical effect in the operation we are now going to perform. Here I have a sheet of glass upon which I will spread a film of iodised collodion—collodion containing iodide of potassium, and we will now immerse this plate in a solution of nitrate of silver, so as to precipitate by the ordinary photographic process, in fact—the so-called collodion process—a film of iodide of silver upon the surface of the plate. That will be precipitated in one or two moments, and then we will expose that film to the action of the spectrum, which we have before obtained on the ground glass. We will remove the ground glass, and substitute for it our prepared plate. Here, you see, we have a yellow film of iodide of silver produced upon that plate. It is necessary first to secure the complete evaporation of the ether in which the collodion was dissolved; that, I think, we have now sufficiently effected, and you see we have a yellow film here. I do not want to expose it too much

even to the light of this gas, but some of you may, perhaps, wonder why I am operating here with this comparatively brilliant light. The fact is, that this gas-light contains very few of those rays which I rendered visible to you on the spectrum, and, consequently, it is incapable of producing any effect on this plate, and I may work with this gas flame for a short time, at all events, with impunity. Now we will expose the plate to the spectrum. I will make a mark here where the luminous spectrum goes to. It is a very rough mark, but it will do for our purpose. I have just marked the extent upon the plate to which the luminous part of the image of the spectrum comes, so that you may be able to judge when we throw the image of this plate upon the screen, after we have brought out our effect, whether what I have said be correct or not, as to these chemical rays existing upon the outside of the spectrum. The spectrum has now acted sufficiently, and I pour upon this plate what photographers term a "developing solution," which is a solution of pyrogallie acid. This enables the surface of the iodide of silver, where it has been exposed to the light, to decompose the nitrate of silver in the presence of this pyrogallie acid, and to produce an image on the plate. You see we have here an image of our spectrum. Now, I will remove the sensitive coating from the plate by means of a solution of cyanide of potassium, so as to make it more transparent in those portions which have not been acted upon by the light. Having thus got our effect, let us examine in what direction that effect has been produced, whether it has been produced, or much of it produced, by those luminous rays, or whether we have been indebted chiefly to the non-luminous portion of the spectrum. I will try to throw an image of our result upon the screen by means of this lens; and now we will interpose our plate, and there is the result we have got. You see a great chemical effect has been produced on the right hand of that little notch which I cut with a strip of wood on the plate while the photographic process was going on. That line marked the extent of the visible spectrum. To the right all is invisible on the plate, and in that part we had the visible spectrum on the screen. You see to what extent in that direction the chemical effect has gone, and how very much more the rays have operated to the right than to the left of it.

I shall now be able only to glance very briefly indeed at the compounds of chlorine. We have the names and composition of these compounds upon these diagrams:—

Compounds of Chlorine.

I. With Hydrogen.

Hydrochloric Acid . . . HCl

II. With Metals.

Protochlorides . . . MCl
Sesqui-chlorides . . . M₂Cl₃
Bichlorides . . . MCl₂
Terchlorides . . . MCl₃

III. With Oxygen.

Hypochlorous Acid . . . ClO
Chlorous Acid . . . ClO₂
Peroxide of Chlorine . . . ClO₄
Chloric Acid . . . ClO₅
Perchloric Acid . . . ClO₇

Chlorine forms only one compound with hydrogen—hydrochloric acid,—from which Scheele first obtained this element. This compound, as I remarked before, was at that time called muriatic acid. With metals it forms four principal kinds of compounds, namely, first the compound in which one equivalent of metal is united with one equivalent of chlorine, these are called protochlorides; secondly, sesquichlorides, or bodies containing three equivalents of chlorine to two of metal; thirdly, bi-chlorides, or bodies containing one equivalent of metal and two of chlorine; and, lastly, ter-chlorides, or bodies containing one equivalent

of metal and three of chlorine. Then we come to the compounds of chlorine with oxygen. These are exceedingly curious bodies, and if time had permitted, I would have shown you specimens of one or two of them and their reactions; but it is impossible that we can do that now. It is very singular that these two elements, which are so much alike in their chemical characters, should combine at all. They are the two most negative elements with which we are acquainted, and yet you see they form this numerous class of compounds. It may, in fact, always be regarded as a rule in chemistry, that, if two elements will unite, then the nearer their affinities, or, rather, the nearer their chemical qualities come together, the more numerous will their compounds be, but, at the same time, such compounds will be very unstable. The two elements now in question form some of the most dangerously explosive compounds with which chemists are acquainted, and it is very difficult to prepare some of them, even in small quantities, without fear of explosion. On the other hand, the compounds of chlorine with metals, and with the positive elements, are characterized by great stability, and if we have in the compounds one equivalent of metal united with one equivalent of chlorine, they are invariably all of a neutral character.

Some of the general considerations regarding this subject I have marked among the following memoranda, to which I can now do no more than refer you:—

1. Chlorine always occurs in Nature combined with positive elements, and chiefly with sodium, as common salt.
2. Chlorine is distinguished for its intense negative energy, and for its capability of exerting its affinity generally at ordinary temperatures.
3. It possesses a very feeble affinity for carbon.
4. Light frequently affects the affinities of chlorine, in the same manner as heat influences those of oxygen.
5. Chlorine exerts great bleaching and disinfecting powers. Its affinity for hydrogen endows chlorine with both these powers.
6. Oxygen, hydrogen, nitrogen, carbon, and chlorine may be considered as the chemical representatives of all the other elements; thus sulphur, selenium, and tellurium are closely allied with oxygen in their chemical habits. Most of the metals bear a strong chemical resemblance to hydrogen. Phosphorus, arsenic, and antimony are closely analogous to nitrogen. Boron and silicon possess considerable likeness to carbon; whilst bromine, iodine, and fluorine are the chemical counterparts of chlorine.

In conclusion, I have very briefly to direct your attention to the remaining elements which belong essentially to inorganic chemistry, and I trust that none of my audience have expected that I intended in these Lectures to give the history of the whole of these elements; it would have been utterly impossible in such a Course of Lectures. I have endeavoured rather to take representative elements, and make these illustrate the action of the chemical force—representatives symbolising the action of corresponding elements in a vast number of instances.

I have treated of oxygen, hydrogen, nitrogen, carbon, and chlorine, as representatives of five great classes of elements. Under these five elements you may group together all the other elements, and you may regard the reactions which we have seen to ensue with these elements as going through their respective groups, to a very great extent at all events. There are, of course, peculiarities in the case of each element; but the general characters of the reactions of these representative elements may be regarded as going through the entire of the five classes at the head of which they are placed.

Vulcanised India-rubber which is worn out, until it has become as brown as the pure caoutchouc, still contains an appreciable quantity of sulphur.—*Dr. L. C. Levoir.*

NOTICES OF PATENTS.

An Improved Grease for Lubricating the Frictional Surfaces of Machinery. C. N. LEZOR. Paris.

THIS lubricating composition is prepared from oil or fatty matters mixed with small quantities of the alkalies, potash and soda, in aqueous solution. The inventor recommends that the materials should be employed in the following proportions:—Of any serviceable description of lubricating oil take 33 parts, tallow 25 parts, caustic soda or potash mixed in equal proportion 2½ parts, dissolved in about 40 parts of water. These ingredients require to be well incorporated by kneading, when they will furnish a very white soft grease, suitable for lubricating the bearings and other moving parts of machinery without having any tendency to corrode the metallic surfaces.

The mixture of materials here specified would result in the preparation of a very crude and partially saponified soft soap. Some alkali would doubtless remain for a considerable time in the free state, and, although this may not exert any deleterious action upon surfaces of iron, there would be every probability of its acting injuriously upon brass, bronze, and some of the softer alloys occasionally used for the bearings of machinery. The want of definite instructions regarding the kind of lubricating oil to be employed with the tallow renders it impossible to define more exactly the chemical nature of the ultimate product. Whether olive oil be used, or any one of the class of mineral products obtained in the distillation of shale or coal, such as paraffin oil, either would equally answer to the term "lubricant;" but inasmuch as these oils differ widely in their behaviour with caustic alkalies, the first only being capable of saponification, the lubricating material would possess different properties accordingly as one oil or the other happen to have been employed in its preparation. Both soft and hard soap dissolved in water, and the same incorporated with various kinds of grease, have received in this country a wide application for lubricating purposes.

MISCELLANEOUS.

Stoppers of Caustic Solution Bottles.—It is well known that the stoppers of these bottles rapidly become incrustated; greasing is of little use, moreover, we have to consider that we may thus introduce fatty acids into the solution; now paraffine answers well: first, because caustic alkali does not act upon it, and secondly, because it perfectly lubricates the surfaces in contact.—*Polyt. Notizblatt.*

A Sensitive Reagent for Sulphur.—By M. Schlossberger.—A solution of molybdate of ammonia in hydrochloric acid diluted with water, possesses the property of colouring blue, if traces of sulphur are present. By this means the presence of sulphur even in a single hair is easily recognisable.—*Polyt. Notizblatt.*

Nitrate of Soda.—Nitrate of Soda in the neighbourhood of the River San Francisco, Bahia, Brazil:—I have the honour to acknowledge the receipt of your lordship's despatch of January 7 last, instructing me to report, after a careful inquiry, on the localities in which nitrate of soda has been found in this province, its state of purity, the cost of extracting and refining it, and the expense of transport to a shipping port. In reply I beg to state that ever since the mention made in my Commercial Report for the year 1856 of the discovery of this important manure in this province I have received undoubted information of its existence in several other localities, and in consequence lost no time in renewing my exertions, with the assistance of a few friends having connexions in the interior, to obtain every information possible thereon. The

information received from several districts is such as to satisfy my most sanguine expectations, especially in the north-east of this province, in the neighbourhood of the River St. Francisco, at a place called "Salitre." In the words of a most distinguished and talented native of the town of Joazeiro, through a valley of sixteen to twenty leagues long, one mass of nitrate of soda is found; in some places on the surface, at others a few feet under; and it contains sufficient manure for exportation for years to come. On the opposite side of the above-named river, near the town of Pilao-Arcado, other deposits exist in equal quantities. The projected Bahia railroad to the town of Joazeiro must pass through the first named district, but those magnificent deposits will only become available when that railroad reaches the St. Francisco. In the interest of the Company and of commerce it is ardently to be desired that its works should be commenced and prosecuted with vigour, as the distance is only 240 miles from the city.—*Extract from the Report of H. B. M. Consul.*

New Process for Preparing Nitrate of Silver.—By M. Greiner.—Dissolve impure silver in nitric acid, and when the liquid is almost neutral and cold, add a solution of sulphate of soda to precipitate the sulphate of silver, which is to be washed in distilled water; after this digest it with heat, with a proper proportion of nitrate of baryta, thus forming sulphate of baryta, to be separated by filtering, and nitrate of silver which can then be crystallised. It remains to be seen whether the product is pure; the facility with which nitrate of silver combines with alkaline nitrates, makes it likely that it would also have a certain affinity for nitrate of baryta.—*Journal de Pharmacie et de Chimie.*

ANSWERS TO CORRESPONDENTS.

* All Editorial Communications are to be addressed to the Editor; and Advertisements and Business Communications to the Publisher at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

C. Bades.—The fault is not in the cyanide solution, but in the way the iron has been cleaned. After it was removed from the "pickle" it should have been soaked in strong soda, and after being washed, instantly dipped into the cyanide solution. When the copper is properly precipitated it should be again well washed. You can get all the apparatus necessary for the electric light and experiments with vacuum tubes at Mr. Ladd's, Beak Street, Regent Street.

D. ONYON.—The subject is rather an intricate one. If we meet with any good information, it shall at once be published. We are obliged for the information and will endeavour to learn further particulars.

Riflemen's Belts.—To polish enamelled leather, take half a pint of the best cream, a quarter of a pint of linseed oil, make them each lukewarm, and then mix them well together. Having previously cleaned the leather, rub it over with a sponge dipped in the mixture; then rub it with a soft dry cloth until a brilliant polish is produced.

A Reader.—We have seen nitro-benzol prepared almost colourless by distilling it by means of steam at a temperature below its boiling point. Distillation in the ordinary way is apt to injure the delicacy of its odour.

Ice.—A correspondent writes:—"A friend of mine in the West Indies having lately seen a paragraph, evidently taken from a Paris paper, of a French gentleman who experimented before the Society of Arts with two quicksilver batteries, and having put one of them in the fire, after pouring in ammoniac, made ice. My correspondent having bought the utensils, is unable to work them, and has therefore requested me to ask your advice and assistance."

Chemistry of Brewing.—Preventing Beer from turning Sour.—We have the following from reliable authority:—"A French chemist has discovered a chemical compound, by which, upon the addition of a quantity of it, according to the quantity of beer operated upon, it prevents the beer passing into the acetous fermentation, and keeps it in a perfectly sound condition for an almost indefinite space of time, no matter the quality of the materials used in its manufacture; but as beer, &c., are excisable articles and the penalties heavy if found adding any substance otherwise than allowed, the discoverer goes to the Board of Inland Revenue, states the discovery he has made, wishes to know if any brewers using it would be prosecuted. The Board reply by saying it must receive a searching analysis by their chemists, to see whether it would be injurious to the consumers. In a subsequent communication from the Board, a reply is given that it possesses no injurious properties, and he is allowed permission to use it. He is about getting a patent for it, as to have used it without the sanction of the Board, prior to obtaining a patent, would have subjected him to heavy penalties."

THE CHEMICAL NEWS.

VOL. IV. No. 90.—August 24, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, Math. Mag. Phil. Nat. Medicina, Artis Obstetrica et Pharmaceutica Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.

IN the latter part of the reign of King Charles X., the celebrated Gay Lussac made a proposition to introduce a different method for the estimation of silver. It had been proved that the method by cupellation gave, even in the hands of very able practical men, not always the same and satisfactory results; and further, it had also been proved, that this method was liable to faults against which it seemed there were no means of guarding. The new method adopted was the volumetrical one. A weighed quantity of the silver to be assayed for its real value is dissolved in nitric acid; another weighed portion of perfectly pure silver is also dissolved in the same acid. A solution of common salt in water is made so as to be of known strength, and so much of this solution of common salt in water is added to both solutions of silver in nitric acid, as is necessary to precipitate all the silver in each of the solutions.

Since common salt undergoes double decomposition in contact with nitrate of silver in such a manner, that nitrate of soda and insoluble chloride of silver are formed, and since common salt precipitates silver always in equivalent proportions, the quantity of the solution of common salt which has been used, can serve as a measure for the quantity of silver in the solution of silver which has been subjected to analysis. In the same way, the solution of pure silver gives the value of the measure, with which the silver to be analysed is to be compared. If, for instance, one gramme of the pure silver had been weighed, and also one gramme of the silver to be analysed, and if of the very same solution of common salt 1000 parts by liquid measure had been necessary to precipitate all the pure silver, and 900 parts only of that solution had been applied to precipitate perfectly the silver subjected to analysis, then the value of the silver to be analysed should be to the value of the pure silver as 900 to 1000. This most excellent method was not only highly satisfactory to its inventor Gay Lussac, but proved to be the same to every one who became acquainted with it. It was very soon adopted by every one who appreciated correctness, and it soon superseded the method by cupellation. Gay Lussac wrote a memoir, in which he gave a description

of his method as it is yet employed, under the title, "Instruction sur l'Essai des Matières d'Argent par la voie Humide; Paris: 1832;" which memoir was translated into German by Liebig, under the title, "Vollständiger Unterricht über das Verfahren, Silber auf nassem Wege zu Probiren; Braunschweig: 1833." It is a most extraordinary proof of the perfectness of this method, which is called the assay by the moist way, that after so many years it has not been changed. It still remains as a monument erected by the practical genius of Gay Lussac.

It may give rise to some astonishment that this method has not been repeatedly subjected to scientific researches, and the results published, were it only for the reason that this method, after having been invented, has come into general practice. In the first place, it must be stated, that the science of Chemistry has been greatly advanced, and although, on the other hand, Gay Lussac himself has published his method, perfectly fit for general use, a great many scientific points relating to it have neither been explained nor touched by him. No doubt the skilful men who in their practice have nearly daily to do with the so-called method by the moist way, have made a valuable collection of many points relating to this method, but none of these has been published; in every manual the general foundations of the practice of this method have been given, but nothing more. Notwithstanding this, it is in this, as in so many other parts of science, there will always be found something valuable when a thoroughly deep investigation is made, and the facts viewed under a somewhat changed light.

I therefore hope, that no one will charge me with temerity, when I, when other more capable men in the use of the method by the moist way keep silent, undertake to investigate that method chemically, and to explain the particulars to be observed in it, and to try according to the best of my capability to review this method by the moist way in the light of the modern science of Chemistry.

I am aware that I am hardly competent to treat the subject according to its value, all be it that my honoured friend, Mr. Van Riemsdyk,² has shown me his method of operating. Part of the experiments mentioned hereafter have been done by me, with the assistance of Mr. Van Vlaanderen.

Although I do not intend to make remarks, neither to give explanation, about all things relating to the method, I have thought it expedient to review it both in a practical and scientific point of view.

As far as the practical application is concerned, I wish to give all that has appeared to me necessary to increased exactness, as well as facility, I have altered the apparatus according to my own experience, and I will

¹ Translated from the original Dutch by A. Adriaani, Math. Mag. Phil. Nat. Medicus Doctor, Fellow of the Royal Netherlands Institution of Engineers, &c., &c.

² A. W. G. Van Riemsdyk, Esq., is a Member of the Supreme Council of the Mint of the Kingdom of the Netherlands,—by the bye, one of the most extensive mint works of Europe, established at Utrecht.

give the reasons for the changes made. I shall be able to prove that my apparatus give correct results, and their simplicity is such that they may be readily constructed from the materials found in every well-arranged chemical laboratory.

The only instrument which must be procured from elsewhere is a balance, and it is just this instrument which is an impediment to reaching absolute accuracy, even when one is in the possession of a balance which is sensible to the one-twentieth part of a milligramme. As far as the method itself is concerned, it is able without any difficulty to estimate the silver to one-twentieth of a milligramme for one gramme of silver.

I divide my research into two parts,—*The Chemical Investigation*, and *The Practical Method*,—and may state at once that by what is called normal solution of common salt, I mean such a solution of that salt in water, that 100 cubic centimetres of it contain at a temperature of 15° C., 0.54141 gramme salt, a quantity just sufficient to precipitate a solution of 1 gramme of pure silver dissolved in nitric acid. By decimal salt solution I mean one part of the same liquid diluted with nine parts of water. I must also mention that I understand by decimal silver solution a solution of 1 gramme of perfectly pure silver in nitric acid diluted with water to 1 litre, also at a temperature of 15°.

Decimal solution of salt and decimal solution of silver have been applied to the same volume, both being of equal strength. 1 cubic centimetre decimal solution of salt precipitates 1 milligramme of silver, and 1 milligramme of pure silver is contained in 1 cubic centimetre of the decimal silver solution.

I. The Chemical Investigation.

Solid Substances in Liquids.—If we wish to become acquainted with the method by which the quantity of silver is estimated, when a solution of silver in nitric acid is precipitated by a solution of common salt in water, it is necessary, in the first place, that we should make a thorough investigation of that which goes on when dissimilar substances are present together in a liquid.

It is easy to say from chloride of sodium there is formed chloride of silver, while at the same moment nitrate of soda is reproduced from nitrate of silver. The chloride of silver being insoluble is precipitated, while nitrate of soda remains in solution in the liquid. It is scarcely necessary to prove that things are not going on in this case in such a simple way; or to say that such though it is the chief action which takes place, is not the only one which is called into play here.

Beside the action of the real chemical affinity, there are in the action which solids and liquids mutually produce, consecutive actions of the so-called physical influences, which here, as in many other instances, play so prominent a part, that even Berthollet felt inclined to give them a first place while engaged in publishing his celebrated work, "*Essai de Statique Chimique*, 1803."

These so-called physical influences are certainly to be taken notice of, even although we know them only imperfectly, and although they are neither well classified nor expressed in laws.

Should we take them for these reasons, as if they were not existing, or should we cast them aside as if they had only a minute influence?

Even he who only makes use of chemistry as a branch of applied science is driven by the necessity of the greatest possible correctness to value every influence,

though he does not care about the name, whether it be chemical or physical; in the same way he who is a scientific chemist by profession makes use of many parts of the chemistry applied to arts in order to obtain more information, for in applied science an important fact is often hidden from which pure science can derive profit; profit, however, not so much in the sense of making money as in the sense for the promotion of true genuine knowledge.

If a more correct idea be formed of what happens when a solution of silver is precipitated by a solution of common salt, then it will be seen that it gives rise to many peculiarities worthy to be studied more closely; and, even although they cannot yet be explained in all parts, they merit a place along with that of the peculiarities of many other substances in action. It may be, therefore, not altogether unfit to begin our investigation by bringing these under a general point of view, or to show at least the relation which exists between them, and in doing so we are sure to obtain more space for the right representation of the phenomena presented by the precipitation of a silver solution by a solution of common salt. In the first place, then, I will take under consideration the position in which solids are placed when in solution in liquids, dissimilar solid substances of course, which, generally speaking, must be considered to exercise a chemical action upon each other; which, however, are either totally or partly prevented from satisfying their chemical action by the interference of so-called physical influence.

There exist a great many instances in which it can be proved, that the fact of a substance *a*, being in solution, can exercise a great influence upon the mutual affinities of two others, *b* and *c*, which are held in solution by the very same liquid. Vauquelin (*Ann. de Chimie*, tome xii.) gives a very simple instance of such an occurrence. He prepares a saturated solution of a salt *a* in water, and afterwards dissolves in the same solution a salt *b*, after which a fresh quantity of the salt *a* can be dissolved by the previously saturated solution of it. The degree of solubility of the salt *a* first depended upon the action which took place between *a* and water; but by the presence of *b*, *a* is again disposed to enter into the solution to a greater extent than before.

It is supposed in this case that the salts do not act chemically upon each other; hence it follows that two salts which have not a chemical action upon each other, if in solution together in the same liquid, have the power of increasing their mutual solubility, and *a*, as well as *b*, endeavour to do so. Like as there is no limit for the physical division of solids, so there is no solid also which may be called perfectly insoluble, provided it admits of very great divisibility. What we are accustomed to call insoluble in chemistry is not really so. The solubility of sulphate of baryta in water, of oxide of tin (stannic acid), in dilute nitric acid, of carbonate of lime in water free from carbonic acid, can be readily proved. Since water possesses the property of keeping in suspension, or even in solution, a great many minutely-divided substances, and since, according to the instance just mentioned, as given by Vauquelin, the solubility of a soluble salt can be greatly increased by the solution of another quite different salt in the same liquid, then the case may often occur that a so-called insoluble substance in water is rendered perceptibly soluble by the presence of another soluble substance, or in case it would have been otherwise precipitated, can be kept in solution. In such cases the chemical affinity gets modified simply by solution, for the substance which we are acquainted with

as being insoluble remains in solution, and presents itself to us in a quite different aspect from that by which it is ordinarily characterised.

Among the instances of the so-called physical influence upon chemical affinity, I may bring here under notice the mutual action of sulphate of soda and chloride of magnesium: both being dissolved in water it is quite dependent upon the temperature in what form they crystallise. In the cold, sulphate of soda crystallises out, chloride of magnesium remaining in solution; at a higher temperature sulphate of magnesium and common salt are formed, and at the boiling point, again, another change takes place,—separation, viz., of a double salt of sulphate of magnesium and sulphate of soda. It is in this way that Balard obtains sulphate of soda from the brine which yielded common salt, merely by means of cooling. (*Regnault, Cours Élément. de Chimie*, p. 577.)

(To be continued.)

*On the Estimation of Tin by Standard Solutions,
by M. SCHUBERT-KESTNER, of Thann.*

THE estimation of tin by standard solutions depends on the transformation of protochloride of tin into bichloride. MM. Streng and Mohr¹ have employed bichromate of potassa, solution of iodine, and permanganate of potassa as oxidising agents. The result of M. Mohr's experiments is that whichever of these bodies is employed the proportion found varies with the quantities of water used, that upon taking a certain quantity of chemically pure tin, the trials made with permanganate of potassa, or any other oxydiser, will not give the weight of tin employed, but always a less weight, a circumstance which has induced him to admit for these estimates an empirical atomic weight for tin (65), differing greatly from the actual weight (59). Even this number is allowable only when operating constantly with quantities of water equal to those which served to determine it.

M. Lenssen² estimates tin by the iodine solution, but he operates in a liquid containing double tartrate of potassa and soda, and bicarbonate of soda in excess. The results M. Lenssen obtained by this method are satisfactory, by using the atomic weight of tin generally adopted (59). We shall see further on why M. Lenssen's results agree.

M. Stromeyer³ having recently occupied himself with the same subject, has succeeded in solving the difficulty. The solution of protochloride of tin is carefully introduced into an excess of sesquichloride of iron. The salt of iron becomes reduced to a minimum according to the following equation:—

It is then estimated by permanganate, as if it were a salt of protoxide of iron. The results M. Stromeyer obtains in this way are very exact. The author adds that such a method of estimating is applicable only in the absence of copper or iron, as these two metals decompose permanganate of potassa, as well as the tin; but it may be of great use in the estimation of commercial salts of tin.

I have endeavoured to determine the causes of the variations observed when oxidising a solution of protochloride of tin, proximately by permanganate of potassa,

and whether, as M. Mohr supposes, these anomalies arise only from the presence of oxygen dissolved in the water. To make these experiments agree better, the solution of protochloride of tin mixed with the proper quantity of water has been instantaneously oxidised by permanganate, so as not to take time into consideration. The irregularities occurring during this operation are shown in the following table:—

c. c.	of Sn Cl ₃ , without	water, required	Permanganate.
2	and 10 c. c. water	"	34'5
2	" " 20	"	34'5
2	" " 50	"	34'5
2	" " 100	"	34'0
2	" " 200	"	33'0
2	" " 300	"	33'0
2	" " 400	"	31'0
2	" " 500	"	31'0
2	" " 600	"	29'0
2	" " 700	"	30'0
2	" " 800	"	28'5
2	" " 900	"	28'0
2	" " 1,000	"	28'0
2	" " 1,200	"	25'0
2	" " 1,400	"	23'0
2	" " 1,600	"	22'5
2	" " 2,000	"	17'0
2	" " 3,000	"	8'0
2	" " 4,000	"	10'0
2	" " 5,000	"	17'0
2	" " 6,000	"	18'0
(A) 2	" " 8,000	"	24'0
2	" " 10,000	"	23'0
2	" " 14,000	"	25'0
2	" " 24,000	"	32'5
(B) 2	" " 24,000	"	32'0

Leaving A and B to rest for ten minutes,—

(A) has required 14'0 of permanganate.
(B) " 25'0 "

The result of these experiments is that the more the solutions are diluted, the less permanganate is necessary until the proportion becomes about 10,000 parts of water to one of tin (100 cubic centimètres of the oxidising liquid corresponding to 1 gramme of tin). From this point the quantities of permanganate necessary are again augmented, and when the dilution is brought to $\frac{1}{24000}$ th as much permanganate is needed as when it was only at $\frac{1}{2000}$ th. The oxygen of the water then seems to have very little action on concentrated solutions, while on diluted solutions its action is very marked. At a certain degree of dilution, however, these phenomena are reversed, and instead of continuing to augment, the sensitiveness of the liquid for oxygen diminishes more and more, becoming gradually reduced to what it was in the concentrated solutions. In the preceding experiments no account has been taken of time; the oxidation always took place immediately after the protochloride was mixed with water. By allowing the very diluted protochloride to remain several minutes before adding the permanganate, a much greater absorption of the oxygen of water takes place, as shown by the Experiments A and B.

If the oxygen of water is the cause of these variations, they ought not to take place when boiled water freed from air is used; and in fact they do not then take place. Water was boiled, and the temperature then lowered to 80°, the protochloride was then introduced and the estimation proceeded with. The following results show that in operating thus the standard does not vary, whatever quantities of water are used.

Protochloride employed.	Quantities of Water.	Standards found.	
		With Cold Water.	With Boiled Water.
2	100	26	26
2	200	23	26
2	300	22	26
2	400	21	26
2	800	19	26
2	900	17	26
2	1,000	16	26
2	1,200	13.5	26

For studying the action of free oxygen on diluted and concentrated solutions of tin, I passed a current of this gas into various solutions of protochloride of tin. For this purpose two flasks, communicating by a tube, are filled, one with a solution of 2 cubic centimetres of protochloride of tin in 100 cubic centimetres of water, and another with the same quantity of protochloride in 1000 cubic centimetres of water. The oxygen current, forced to traverse the contents of the first flask before arriving at the contents of the second, during an hour, the liquids in the two flasks filtered and tested by permanganate of potass, yielded the following results:—

	c. c.	c. c.
1st Flask, containing 2 Sn Cl in 100 water, required 25.5 permanganate.		
2nd Flask	1000	9.2
2 c. c. Sn Cl, in 1000 of water, without oxygen current, 16.0		"

The first flask contained the strongest solution, and received the oxygen first, and absorbed only an amount of oxygen represented by 0.5 of permanganate; while the metal solution of the second flask absorbed a quantity represented by 16 — 9.2 = 6.8 of permanganate. The same experiment repeated by employing only 50 cubic centimetres of water in the first flask, and by continuing the oxygen current for two hours and a-half gave the following numbers:—

1st Flask, containing	50 c. c. of water,	26 permanganate.
2nd Flask,	" " " " 1000	" " " " 3.2

In this case the concentrated solution of protochloride of tin did not absorb oxygen, while the diluted solution absorbed a quantity equivalent to 16 — 3.2 = 12.8 of permanganate, that is to say, nearly half the oxygen necessary to oxidise the protochloride completely.

M. Mohr's experiments prove¹ that the oxygen of water has not the slightest action upon salts of protoxide of iron, whilst under the same conditions the protoxide itself oxidises immediately. M. Mohr has taken advantage of this property to estimate by means of permanganate the oxygen dissolved in water. It is interesting then to observe whether there exists between protochloride and protoxide of tin a difference of affinity for oxygen, analogous to that distinguishing the salts of iron of the oxide. This analogy, in fact, exists, only the reactions are inverse; that is to say, protoxide of tin manifests no affinity for free oxygen, while, as we have seen above, the protochloride combines more or less rapidly with this gas dissolved in water.

(To be continued.)

On Obtaining Thorina and Tantallic Acid in Crystals, by MM. A. E. NORDENSKJOELD and J. J. CHYDENIUS.¹

THE thorina employed was extracted from orangite by treating that mineral by hydrochloric acid, separating the silica, precipitating by ammonia, redissolving the precipitate in hydrochloric acid, neutralising by ammonia.

and precipitating the thorina by sulphate of potassa, as double sulphate of potassa and thorina. This salt washed with a solution of sulphate of potassa was dissolved in water, and the thorina precipitated by ammonia. The previously washed thorina was again dissolved in nitric acid; then, for the last time, precipitated by ammonia, washed, and calcined. It had a slight yellowish colour. Density 9.08.

In one experiment thorina was crystallised by exposure to the temperature of a porcelain furnace in platinum capsules, with borax, in the glass formed by which the crystals were found. In another experiment a like result was obtained, with boracic acid, by Ebelmen's method. Thorina formed small brown or white prismatic crystals, sometimes ending in a base, sometimes in a quadrangular pyramid, the faces of which are sometimes hollow like those of sea salt. The authors refer these forms to the type of a prism with square base. The angle of the octohedron face on the adjacent face of the prism would be 102° 30', which greatly resembles that of an octohedron of oxide of tin, rutile, and zircon. Thorina would then be isomorphous with these three oxides, and would then have the formula ThO₂, instead of ThO or Th₂O₃.

The density of crystallised thorina is 9.20. Tantallic acid extracted from tantalite (hjelmite) of Nya Kärarivet, and freed from tungstic acid and oxide of tin by fusion with a mixture of sulphur and carbonate of soda, was mixed with four times its weight of salt of phosphorus. After exposure to the heat of a porcelain furnace, and being treated by hydrochloric acid, it yielded a gelatinous mass on the addition of water.—*Poggendorff's Annalen.*

Notes on the Extent to which Mercury Volatilises along with the Vapour of Water at 100° C., by J. W. MALLET.

IN Berzelius' *Traité de Chimie* it is stated that Stromeyer drew attention to the fact of the evaporation of mercury in considerable quantity at 60° to 80° C. with the vapour of water, the more volatile substance carrying with it the less volatile, as in the case of a solution of boracic acid when heated.

This fact does not seem to have been very generally noticed by the compilers of chemical text-books in treating of the history of mercury, though it was always stated that the metal is capable of volatilising to a very slight extent, even when alone, at the common temperature of the atmosphere. Some doubt, too, would seem to have been thrown upon Stromeyer's observation by the experiments made, under peculiar conditions, by Fresenius, and reported by him in the appendix to his *Treatise on Quantitative Analysis*. It was found that 6.4402 grm. of mercury, covered with a considerable quantity of water, and heated to the boiling point of the latter for a quarter of an hour, lost but .0004 grm., while exposure to the air at summer heat for six days produced a further loss of .0005 grm.

I have lately observed the tolerably rapid evaporation of the metal with steam, produced not from a mass of water covering the quicksilver, but from a porous and highly absorptive clay which was dry to the touch, but gave off some eight or ten per cent. of water when heated to 100° C. A specimen of this soil had been in contact with mercury, and several grms. of the metal in small globules had become mixed up with the mass. It was placed in the common copper box with double sides which serves as a steam-bath, and exposed to the temp-

¹ *Traité d'Analyses par Liqueurs Titrées*, p. 260.

² *Poggendorff's Annalen der Physik und Chemie*, vol. cx., p. 642. 1860 No. 8.

ature of boiling water. In half-an-hour I was surprised to see that the little piece of glass tube through which the heated air and vapour from the inside of the steam-bath escapes was coated with a bright specular deposit of metallic mercury. This was brushed off, and the tube replaced, when again it became in a short time similarly coated. The steam bath was kept in constant use in drying this and other specimens of soil for twenty or thirty hours, and in this time between four and five grains of mercury was collected from the glass tube. Doubtless the condensation of the mercury vapour on the latter must have been far from complete—a large proportion of mercury probably escaped into the atmosphere. At any rate it seems clear that the metal can volatilise in very considerable amount when surrounded by vapour of water at $100^{\circ}\text{C}.$, and not at the same time pressed upon or affected by the cohesion of a mass of liquid water. Hence an obvious necessity for thoroughly effective condensation when mercury is to be determined in its compounds by ignition with soda-lime.—*American Journal of Science.*

On the Composition and Properties of Permanganic Acid, by M. H. ASCHOFF.¹

MR. PHIPSON'S assertions relative to the non-existence of permanganic acid, already refuted by M. Machuca, are further contradicted by those of M. Aschoff. Having occasion to occupy himself with these inquiries, M. Aschoff has entirely confirmed M. Mitscherlich's long-known views relative to the composition of permanganate of potash. He also proved that violet permanganate becomes changed to green manganate with disengagement of one atom of oxygen, and that the green solution again becomes violet by the action of carbonic acid with a deposit of peroxide of manganese, according to the equation $3(\text{K.O.MnO}_3) + 2\text{CO}_2 = \text{K.O.Mn}_2\text{O}_3 + \text{MnO}_2 + 2(\text{K.O.CO}_2).$

The author afterwards occupied himself with preparing anhydrous permanganic acid. He finds that this preparation can be made without danger, even when operating with 20 grammes of permanganate, by taking care to cool the sulphuric acid (1.845 density) with a refrigerating mixture, and by gradually introducing the permanganate, which must be free from all chlorinated combinations.

The dissolved permanganic acid colours the acid dark green, forming at the same time some oily drops, which fall to the bottom of the vessel, and which, after a time, or rather when the mixture is heated, disengage oxygen. Manganate of potash behaves in an analogous way. There is always a deposit of peroxide of manganese, the manganic acid immediately decomposing into peroxide and permanganic acid.

Permanganic acid forms a dark brown-red liquid, fluid at 20° , very unstable, attracting humidity and decomposing with disengagement of oxygen. It gives no trace of vapour in an exhausted receiver, and when heated to above 65° it detonates violently with flame, and is transformed into sesquioxide of manganese. Its composition answers exactly to the formula Mn_2O_5 .

When permanganates or manganates contain chlorides the phenomena are different, and the yellow vapours obtained by M. Dumas² are produced by adding sea salt

to a mixture of permanganate of potash and sulphuric acid.

M. Aschoff has not succeeded in condensing a sufficient quantity of these vapours for analysis; but he has collected and studied some small drops analogous to anhydrous permanganic acid, which are also isolated in this experiment, and the composition of which answers to the formula Mn_2ClO_6 . This body may be a new combination or a mixture of anhydrous permanganic acid and a chlorinated combination of manganese.

TECHNICAL CHEMISTRY.

On the Manufacture of Iron,¹ by E. RILEY, F.C.S., late of the Dowlais Iron Works.

(Continued from page 98.)

In rolling the flange, or American rail, a particular description of cold short iron was made for the flanges to stand the strain that there necessarily must be from the rails being rolled edgewise, and the flanges not travelling at the same speed (from the less periphery of the rolls) it was necessary that the flanged portion of the rail should slip; and partially on this account, and also on account of the flange becoming colder than the mass of the rail, it was difficult to obtain a perfect flange, unless a peculiar description of iron was used. This iron was made generally with forge cinders and Welsh ironstone, without any red ore. In the bridge rail, which was rolled flat, head up and down, the iron was only likely to rip by becoming cold, and was not submitted to so great a strain as with the flange rail. For common American rails the slabs for the heads were frequently not made more than three-quarters of an inch thick, and the rails were only single-heated.

The way in which a rail has been piled, and the thickness of the top slab for the head, may be easily determined by filing a section of the rail smooth, and acting on the surface with dilute mineral acid, which dissolves the iron and leaves the cinder in the welds or joints intact.

Rails being submitted to a different strain to other descriptions of iron, it was soon found that fibrous iron, such as is used for making cable bolt was not adapted for rails, as the iron was too soft, and strips or ribbons soon began to pare off the rails. Various means have been adopted to make iron crystalline and hard. As a rule, the more you roll iron the more fibrous it becomes, up to a certain point, and for this reason many engineers have the slabs for the heads of the rails hammered, so that they may only be submitted to the drawing action of the rolls once. Since the introduction of the oolitic iron ores it has been found that, by smelting them with a mixture of a little cinder and clay ironstone, that a peculiar description of cold short crystallised iron is produced, and this iron has been very largely used for the manufacture of the heads of rails. The peculiar description of this iron is due to the phosphorus which the oolitic ores contain. Phosphorus has the property, when alloyed with iron, of making it work soft and cold short.

Rails made with this iron have been very favourably reported on by engineers. The iron, although hard, is very weak, and the author's opinion was that hard iron might be made with equal advantage by the use of manganese, without, at the same time, reducing the strength, as you do when phosphorus is present.

Some foreign engineers have even gone to the length

¹ Monatsbericht der K. Preuss Akademie der Wissenschaften zu Berlin. Poggendorff's Annalen der Physik und Chemie, vol. cxi.

² Annales de Chimie et de Physique, Second Series, vol. xxvi. p. 81.

of making it a clause in their specifications for rails that they shall break when a given weight is let fall upon the rail resting on bearings at a specified distance apart.

Single-heated rails require about 12 cwt. of coal to the ton, on an average, and double-heated about 16 cwt.

The author, after apologising for the very brief way in which he had considered the various processes in the manufacture of iron, next proceeded to consider some of the recent improvements that had been suggested and carried out for the manufacture of iron and steel.

The most important, perhaps, was the Bessemer process, which, when first put forth by Mr. Bessemer, in 1856, caused quite a sensation in the trade. The author was, at that time, at the Dowlais Works, and made a series of experiments on the process, which were detailed. The results of the experiments were, that only from the very best descriptions of foundry iron could wrought iron be produced which had at all the character of ordinary bar iron, and even this was of a peculiar crystalline structure, and had the appearance of burnt iron. When the ordinary forge pig, used for making bars and rails, was operated on, nothing could be done with it at all. The iron, after blowing and casting, when submitted to the action of the squeezer, crumbled all to powder and dust; and it was only by using very great care that a piece was made into a bloom and passed through the rolls, the bar was as brittle as glass, and broke, when struck, in all directions, longitudinally and transversely. The same results as the above were obtained by experiments at various other works, and only when such pig as the best Blaenavon Foundry, foreign pig, or pig made from spathose iron ore was used, that any good results could be obtained.

The author investigated the cause of the failure of the process, and on analysing samples of the pig, and the iron after blowing, he found that the whole of the carbon and silicon had been separated absolutely, as not a trace could be found; whereas the sulphur was only slightly diminished in quantity, and the phosphorus, if anything, increased. From the above it was evident that the non-separation of the latter elements was the cause of the failure, in a great measure, with ordinary white forge pig.

Mr. Bessemer instituted a series of experiments on his process, and erected works at Sheffield to carry it out practically. He soon found that he had been in error in using some of the best description and highest-priced irons, as there were others in the market which were far cheaper and much more adapted for his process. On analysis it was found that the grey pig made in Cumberland and Lancashire from the red hematites was nearly free from sulphur and phosphorus, containing not more than .05 per cent. of the former, and .10 per cent. of the latter. This iron is very siliceous, but by blowing the whole of this is separated; by blowing this iron, and adding after the blowing some metallic manganese, or an alloy of iron and manganese, iron or steel of any quality could be made. The author, before considering the condition in which he considered the Bessemer iron to be, detailed more experiments he had made on wrought iron in a fused state.

The results of the experiments (which had been frequently repeated) were that if the very best fibrous cable bolt iron was melted in a clay crucible (so as to be kept away from carbon), a crystalline fused button was obtained, which had somewhat the appearance of antimony. This iron, when worked by a smith, was very redshort, and after welding it broke all to pieces as the heat came down, although at a low temperature it

worked tolerably well. It was, in fact, in the same condition as the Bessemer iron, and was in this state useless. On adding to the pieces of iron (from 1 to 1½ lb. were used in each pot), a very small amount of metallic manganese, from 1½ to 3 or 4 per cent. in various experiments, it was found that the lower quantity of manganese restored all the original properties to the iron, and that anything could be done with it, and it would work at all temperatures. The higher proportions of metallic manganese gave the iron a steely character, and in fact converted it into a low steel. Experiments were also detailed on the reduction of wrought iron in a fused state direct from the best clay ironstone (by leaving an excess of oxide of iron in the cinder); the iron thus produced was useless, as it would not work at a high temperature, but worked moderately well at a low heat.

The author considered that a small amount of carbon was essential to wrought iron, and by the process of melting, or the Bessemer process, this small amount of carbon was removed. By the introduction of metallic manganese, the carbon was taken by the iron, and the manganese would become oxidised, and unite with the silicon or other impurities in the iron. It was well known that pig iron, made from the spathose iron ore, not only contained a high per-centage of manganese, but also a higher per-centage of carbon than any other description of pig. This iron was generally white, the author never having seen it better than mottled, and he believed great difficulty would be experienced in getting it grey. Manganese certainly has the property of fixing carbon in iron in some way not very well understood, and when this metal is alloyed with iron he considered that the manganese would be completely separated before the carbon was touched, and in its separation the oxide of manganese, being an excellent flux, it would have a tendency to separate the impurities in the iron.

The reduction of manganese from its ores, and the difficulties attending it, were mentioned in illustration of the properties of this metal, and the author considered that the application and use of manganese in the manufacture of iron was most important.

The author then referred to drawings of the vessel Mr. Bessemer used for his process. One of the great difficulties was in getting the tuyeres to stand, as the fluxing action of the oxide of iron and the temperature in the blowing vessel was very great. In several instances a whole fire-brick had been fluxed away in twenty minutes. By using powdered sandstone, known as "ganister," the fluxing action was not so great, and a further improvement had been made by introducing the tuyere from the top, and making it altogether independent of the vessel, so that it could at any time be withdrawn and replaced by a new one.

Various other processes for the manufacture of steel were commented on, amongst others Uchatius', Mushet's, and puddled steel. The author considered that puddled steel was liable to be wanting in uniformity.

Much had been written on the composition of steel, and various theories had been propounded as to its composition, and the elements requisite for the production of the best varieties of steel. M. Frémy, had published a very extensive series of experiments, and he was of opinion that iron in its three states—cast iron, steel, and wrought iron—is due not only to the different proportions of carbon they contain, but also to the presence of nitrogen. M. Mushet, again, has started a theory that titanium is essential in the manufacture of steel.

It was a well-known fact that cyanides have the property of converting iron into steel, and after the very

elaborate investigation of M. Frémy, in which he showed that nitrogen assisted very materially the formation of steel, the author was of opinion that nitrogen might act in a somewhat similar manner to manganese—viz., as a carrier of carbon, but he was hardly disposed to think that nitrogen was a constituent part of steel. The formation of steel with pure carbon and iron was discussed, and it was thought that further investigation was necessary to prove if nitrogen was or was not a constituent part of the best varieties of steel.

With regard to titanium, this metal had a great affinity for nitrogen and carbon; and if nitrogen is requisite in the manufacture of steel, it is possible it might act as a carrier of nitrogen and carbon. A large sample of titanium (in a pure state), obtained from the hearth of an old blast-furnace, was exhibited.

The author concluded by pointing out the difficulties that there were in accounting for the different varieties of iron which were due, in some cases, to physical, and in others to chemical differences, in their constitution, and at times, perhaps, both combined. It was only by observation and carefully conducted experiments that the true causes could be determined. He was ready to admit that our knowledge was limited on the subject, and he must plead this as an apology for the imperfect way in which he had treated it.

On White Gunpowder, by F. HUDSON, Esq.

HAVING lately prepared different samples of white gunpowder (according to the receipt of Dr. J. J. Pohl, given in the CHEMICAL NEWS, July 6) for some military engineering experiments, I have tried the process of separately grinding the materials, viz. chlorate of potash, ferrocyanide of potassium, and cane sugar, and then mixing them; also grinding them together with a little water added, and then dried at a temperature of about 150°. I find that those samples which were prepared moist and then dried are more easily exploded than those prepared by the dry process. In fact, one sample exploded in an open porcelain dish by simple friction with a spatula with which one of my assistants was crushing some of the larger pieces. Through the explosion he was laid up for several weeks and nearly lost his eyesight. No samples prepared dry are as explosive as those prepared moist, the addition of water causing a more perfect mixing of the particles of its chemical constituents than can be effected by the dry grinding process. This accounts for the greater danger attending the use of white gunpowder prepared in the moist way.

A cannon loaded with the white powder goes off on the application of a few drops of sulphuric acid (equally as well as with a light applied) to its touch-hole.

This property of the gunpowder may possibly be applied to some advantage in the construction and preparation of bomb shells for long ranges. The shells would not explode (if filled with the white powder and containing a glass vessel with sulphuric acid) until they struck the object. No useless explosion of the shell could take place in the air, as is too often the case with the ordinary fusée shell.

Its expansive or explosive force is also twice that of common gunpowder. In all experiments performed with this white gunpowder care must be taken not to compress it too violently; otherwise accidents may frequently occur. A blow with a hammer upon stone with some of the powder upon it explodes all samples that I have prepared.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

A Course of Two Lectures on Musical Acoustics, and on the Physiological and Psychological Causes of Musical Harmony and Discord, by Professor HERMANN L. F. HELMHOLTZ, of Heidelberg.

LECTURE II.

I HAVE had the honour of bringing before you, in my first Lecture, the theory of the composition of waves of sound; at first, the composition of such waves as were of independent origin, and where the composition was a real composition of different systems of waves. I have also explained to you that a wave of any arbitrary form can be considered as a composition of a number of waves of simple form—of waves in which the motion of every particle corresponded to the motion of a pendulum, and calling [these vibrations simple vibrations, we may call such waves simple waves. Therefore, a wave of any other form can be considered as a composition of a number of simple waves. It is shown by the French mathematician that this is always possible, and that any form of wave can be composed by simple waves into one, so that the intensity and the phase of every small wave is known, if the form of a complex wave is at first given. Now, this composition of a complex vibration by simple vibrations is only an imaginary composition. We may consider it in the same way as we may consider every quantity, every number, as a sum of parts. Further, we find that this composition, which is a sort of composition of simple waves, is not only an imaginary composition, but that the human ear makes the same analysis of complex waves as if they were really composed by simple waves. My last experiment was on the monochord, where I tried to show you that, in the sound of the string, if I move the whole string, there, the simple sounds are contained which must be composed in order to get the whole motion of the string.

Now, you will usually find it very difficult to hear the harmonic sounds of the string—to hear the sounds corresponding to the simple vibrations of the string which are kept together in the whole motions. These harmonic tones have been known for a long time, but they have been commonly considered as rare and accidental phenomena of small intensity and of small importance. Philosophers believed they were of small intensity, because it was difficult to hear these tones. But this difficulty is of a very peculiar kind. We should think that nothing could be easier than to feel the sensations of our nerves; but that is indeed not so simple and not so easy as it appears. We are exercised and educated for using our senses, and even in the most common perceptions by our senses there is more exercise than we commonly are inclined to guess. We are exercised to judge by the sensations we get of the real nature and form and quality of the external objects which surround us, and we accomplish this business with the greatest accuracy—with really astonishing accuracy. But we are also in the same way exercised to abstract from all those parts of our sensations, which are necessary for the comprehension of external objects. Every one who has studied the subject of visual phenomena and other sorts of internal sensations, knows how very difficult it is to be attentive to the sensations which are excited by the interior irritations of our nerves. There are a great number of phenomena in the eyes. For instance, there are little filaments which swim about in the vitreous humour, which are only seen if the eye is diseased. And you will remember the celebrated experiment by which the French philosopher excited the curiosity of King James I. of England and his courtiers. He found out that there is a blind spot in every eye, and

that there is a part of the object of vision which is not seen at all. I shut my right eye and look straight forward with my left eye, and bring this piece of red sealing-wax in front of it. If I bring it here I see it, if I bring it there I see it, and so on, but there is a place where it is not seen. Now I suppose that everyone of you who has not made this experiment but whose attention has been drawn to it by others, will hardly believe that—you will doubt it. But such a spot is in every eye. Take another phenomenon of the same kind. Mr. Wheatstone has shown that the correct perception of the dimensions of every object before our eyes depends upon the comparison of the two different images given by our two eyes. You all know that this can be quite clearly proved by the stereoscope. Now, if you look at any solid object before you, I doubt that you will be able to perceive that the condition of the form of the object depends upon the union of the two perspective images which are given by both your eyes. Now, the same difficulty exists for the harmonic tones. If we hear the sound of a string, we always hear the fundamental tone accompanied by a number of harmonics. This whole sensation composed of the fundamental and the harmonics we consider as the sensual sign for the sound of a string. We perceive by this complicated sound that the string is tuned. If there is another combination of harmonic sounds, we guess that there is another instrument sounding. So that we are exercised to distinguish this complicated sensation; but we are not at all exercised to distinguish and perceive the simple elements which are contained in such a complicated sensation: therefore this difficulty of perceiving the harmonic tones is not caused by the small intensity or rareness of harmonic tones; it is not the difficulty of sensation; it is only the difficulty of perception of these tones. It was, therefore, quite wrong to suppose that these harmonic tones are rare or accidental phenomena. Although it is very difficult to hear them, and it requires much exercise, and a peculiar help that we may succeed in directing the attention to these tones. I must say I have exercised myself much in different ways to hear the harmonic tones, but I was always doubtful as to their intensity; and I could not succeed in comparing by the ear alone their intensity in different instruments. The enquiry of the unassisted ear is of great importance in these researches, because it is necessary to show that harmonic sounds are heard even by the unassisted ear. Now, I strove to find a method for hearing the harmonic sounds more easily, and for becoming sure that there was in the tone of any instrument such harmonic sounds, or that they did not exist; and at length I found a method which is quite convenient and simple. I use for that end these glass spheres; they are tuned to different pitches. Here you have a sphere which is tuned to B flat. If I bring the tuning fork before the mouth of the sphere, the air resounds and gives the sound of the tuning fork, and always with great intensity. If the note which corresponds to the pitch of this sphere is produced in the external air, then the interior air of the sphere is violently shaken and vibrated. If I place this sphere to my ear, then I hear the note of the sphere. Every tone when this note is produced in the outer air, be it a fundamental, or be it a harmonic sound, or as a part of a great mass of different sounds. So that I hear, then, this sound corresponding to the pitch of the sphere with great intensity, and all the other sounds which are produced in the same time come to my ear with much less intensity; so that it is very easy to find out if there exist any harmonic tones of a given pitch in any mass of sounds which are produced together in the outer ear. Now, by this means it was very easy to find the harmonic sounds of all musical instruments. I find that there are very few instruments entirely free from harmonic sounds. The best method for getting really the simple sounds is this which I have applied—to bring the tuning-fork before the sounding cave filled with air, which is tuned to the

same pitch. Therefore this kind of sound is really simple sound. We can produce the same kind of sound also from the stopped organ pipes. They gave simple sounds accompanied with a little noise of air. This is a sound of the same kind. The sound of the pipes is not quite so pure as the tuning fork, but it is nearly devoid of all harmonics. Now, the sounds of all other musical instruments contain harmonic sounds of more or less intensity. The most similar to the stopped pipes of the organ are the open pipes; you hear these a little more clearly. The sound of the open pipes, if they have a great section, contains only the first and second harmonics; and if they have smaller sections then the sound is more sharp and it contains more harmonics—to the fifth or sixth. You hear that these sounds are sharper; they are so because they contain more harmonics. Now, these harmonics always give consonant intervals when connected with each other: but the higher harmonics give dissonant intervals,—they are nearer; and therefore such instruments which have very high harmonic sounds sound sharp, and have something disagreeable in their quality of sound. If you will compare the sound of the stopped pipe, or the sound of the open pipe, and the sound of the reed pipe, of the same pitch, you may also perceive that the simple sound appears to be lower than the complex sound of the reed pipes. The fundamental sounds of those two pipes are really the same, but the reed pipe contains high harmonic sounds and therefore the one sound appears to be higher than the other sound, and you hear this difference very plainly. Now, it is not possible, by these means, to ascertain the intensity of harmonic sounds. This can be done for some instruments by mathematical theory. The mathematical theory of the motion of strings is able to give for different methods of exciting the string, the amplitude of the harmonic sounds. For the piano, if its common point where the string is met by the hammer, is $\frac{1}{4}$ th of its length, you have the fundamental sound and the different harmonics. The 8th harmonic is wanting, and the higher harmonics are very feeble, if the hammers are covered with leather, as it is common. Here you have the same for the guitar, if the same point of the string is excited you see the 8th is also wanting. Here also you have the harmonic sounds for the violin, the first sounds are of less intensity than those of the piano or the guitar, but the higher harmonic sounds are not wanting; and therefore the sound of the violin is sharper than the sound of the piano and guitar. A very striking and interesting example of changing the quality of the sound is given by the reed pipes, if they are connected with different tubes filled with air. The human throat contains such a reed pipe in the nerves, and the cavity of the mouth represents the tube which is connected with the reed pipe. Now the cavity of the mouth can be tuned by changing its volume and its opening to different pitches. And we find by enquiring into the quality of the sound with these spheres, that the harmonic sounds of the human voice are different for different vowels, and that different vowels are produced by giving to the cavity of the mouth a different pitch. We can do the same by the reed pipe. The theory of producing vowels in this way was first given by Mr. Wheatstone after the experiments of Mr. Wills. Here I have a common reed pipe of a very sharp sound, it is like A spoken through the nose. Now the pitch of this reed pipe is B, of two feet length, given by organ pipes. If I put upon this a glass sphere, which is tuned to the same pitch, you have a sound like oo. If I put upon it a sphere tuned an octave higher, you have o. If I put upon it a sphere two octaves higher than the first one, you have au, and so on. In this way different vowels can be produced, and are produced in the same way by the mouth. These harmonic sounds which are near to the sound of that sphere with the sounding cavity, are always produced with greater strength. That the cavity of the mouth is tuned to different pitches, can be immediately

ascertained by tuning forks. You saw that the sphere resounds for this tuning fork. If I put my mouth into the position for giving the vowel *o*, you hear the resonance of the tuning-fork. The pitch of the mouth is the deepest for *oo*, and then you can get *o*, *aw*, *ā*, *ah*, for the higher vowels, and so it goes on from *ah*, *a*, *e*, *ee*. This other tuning-fork is $\frac{1}{2}$ th higher than the first, and resounds for *ah*. If I put my mouth into the position of *o* or *oo* you hear nothing. In this way, therefore, you can ascertain the pitch of the cavity of the mouth; and it is stated by the theory of Mr. Wheatstone that those harmonics which are near to this pitch, which is constant for every vowel, and is the same for female and male voices and voices of children,—the harmonic sounds near to this pitch are of greater intensity, and the others of less intensity; and by this composition the vowels are distinguished. Now, it was a question of great importance for the physiologist to ascertain whether such sounds can be also composed by their harmonics not produced in the common way. Because, by such experiments it was possible to ascertain if only the existence and intensity of harmonic sounds is sufficient for producing a given quality of sound, if there are also other differences, if there are other influences necessary for getting the quality of the vowel sound. For this end I have composed an apparatus consisting of some tuning-forks. Every tuning-fork is connected with a sounding cavity, a green cylinder, and put between two branches of an electric magnet. The electric magnet is magnetised by an interrupted galvanic current. The galvanic current is produced by a battery; the interruption is caused by the vibrations of another tuning-fork, the ends of which are connected with the platinum wires, and dipped into mercury if the tuning-fork is swinging, so that by the vibration of this fork the current is interrupted, and we have here 240 interruptions of the current in a second of time. The first tuning-fork in the sounding cavity makes 240 vibrations in a second; the second makes twice as much, the third three times as much, and so on. So that the other tuning-forks give the harmonic tones belonging to this fundamental sound. If I let go the interrupted current through the spirals of the electromagnet, then the tuning forks are brought into vibration because at every magnetization of the iron they are attracted and then go back and then are again attracted, and so on, so that they go in continuous vibration. As long as the ends of these resounding cavities are closed, you will not hear the sound of the tuning-forks, or will hear only a very small intensity. If I open the ends here by a little key, then you will hear the sound, and in this way I can alter the intensity of the sound by opening completely or incompletely the mouth of the cavities, and so I can compose the fundamental sound with any given number of harmonic sounds. This is the fundamental sound; the higher sounds are very feeble; the sound becomes similar to *o*, and, therefore, I make *o oo*. The higher tuning-forks give *a* or *ah*, or the German pronunciation *a*, *o*, *oo*.

In this way, therefore, we can compose artificially the quality of these sounds. You will hear it better perhaps after the end of the Lecture, if you come nearer to the instruments. The sound is a little feeble for a great room, and I cannot strengthen the intensity of the current, because then the sparks become too intense, and volatilise the mercury. So, therefore, it is possible to compose in this way the different qualities of sounds, and to make them similar to the sound of the different musical instruments. The quality of the sound of the vowels is a very favourable example for that, because the vowels have only a musical sound, and other noises which commonly accompany the sounds of other instruments, as the sound of the rushing of air, or the rubbing with the bow on the string of the violin, and so on, are wanting in the vowels, and the vowels are different only by the musical part of their sound, and of course we can only imitate the musical part

of the sound by this tuning-fork. The fundamental question to decide by these means, if only the existence and intensity of the harmonics is wanted for giving equality of the sound; if perhaps also the difference of phase is different, and has influence upon the equality of sound. For showing the sense of this difference I have here the wave-machine of Mr. Wheatstone which I suppose you have often seen. You see here [pointing] a wave of long vibration, and there, one of shorter vibration, where two waves come to every one wave of the higher. The one corresponds to the fundamental sound, and the other to the octave. Then the upper curve shows the combined vibration. You see at present the hills of the inferior wave correspond to the hills and the valleys of the superior. There you will see that the phases all agree; both are coinciding in these two and they give here [pointing to the upper row] these greater heights. We can alter the figure and get different curvatures. Now, by these experiments I found out that only the intensity of the harmonics is wanted, so that all these curves we get above would correspond to the same quality of sound, and that gives no difference of quality of sound, so that only the existence of these is what we want. Therefore the quality of the musical part of the sounds is only determined by the existence of the harmonics. So much about the quality of the sound.

I come now to the influence of the harmonic sounds upon the consonants and dissonants. For finding the cause of the dissonance of two musical sounds we must consider another phenomena, the phenomena of interference of sound. Two sounds can be combined in that way,—two sounds of equal pitch can be combined in this way, that every sound gives an impulse to the air in the same direction, then the intensity of the two sounds is strengthened, they help each other, the vibration of the air becomes greater, or two sounds of the same pitch can be combined together, so that if the one gives an impulse the other goes back, and the impulses are given alternately. Here the motions of the air corresponding to these two sounds are contrary—opposite—and destroy each other. We may combine on the wave machine of Mr. Wheatstone two sounds of the same pitch. Here we have the combined wave. The hills correspond to hills, and the valleys to valleys, therefore in the combined wave you have higher hills and deeper valleys. If we alter the phase of one of these so that hill corresponds to valley, and valley to hill, then you see that the composed curve becomes a straight line. There the hills fill out the valleys of the other line which corresponds to the same point. The two sounds destroy each other, their impulses upon the air are of opposite direction and they destroy each other; so that the air which is shaken by their single sound becomes quiet if both the sounds are combined. Now if the air is quiet we hear no sound. We can produce such a combination by the sirene you saw only lately; because I can here alter the position of the holes of the upper box. I can put this box in such a direction that the holes are opened at the same time and the impulses of both boxes come to the ear in the same time or I can put them in that position that the impulses come alternately, then the sound is destroyed. It is not completely destroyed, because the motion of the air produced by the sirene is not quite simple, and therefore the form of the hills does not correspond exactly to the form of the valleys, and there remains a small intensity of sound. The fundamental sounds destroy each other; but the first harmonic sounds remain; therefore, though the sound becomes more feeble it does not quite cease, and goes up in its higher octave. We have, you hear, alternately greater and smaller intensity, coincidence and interference. Now, if I turn round the axis of the upper box, then I come at first to two points of coincidence and interference and again a point of coincidence and interference, and so we have alternately coincidence and interference. We have, then, a phenomenon which is called beating of the sound.

Now, you know that, if I turn the axis one way, the pitch is heightened, and the other way it is lowered. Therefore, you see that, by giving to the upper box such a motion that the pitch of the sound is a little altered, then we get alternately coincidence and interference, this strengthening or lessening of the sound. So that, therefore, by altering the pitch of one of these sounds by a small quantity, we get this phenomena of beatings. The phenomena of beatings can be produced on all other musical instruments. If we connect two sounding instruments which have nearly the same pitch, but not quite completely, the number of the beatings is always corresponding to the difference of the number of the vibrations. The beatings are very complete. If we have simple sounds, as, for example, by two stopped pipes—when they are of the same pitch you hear no beating, but if I alter the pitch of one, the beatings are heard very distinctly. Here the beatings are separated merely by complete intermittence of the sound. If I take two other pipes which have the harmonic sounds, then the beatings are not so complete, because, during the time where the fundamental sound ceases, the first harmonic sound is strengthened. I take two of these metal pipes, and at present you have an unison, but by altering the pitch of one, the beatings are produced. In the same way the beatings can be produced by other musical instruments. Consider what takes place in the ear during this time. If the tympanum of the ear and the air in the ear is not vibrating, if there is repose, then we still have no sensation at all—no sound. The phenomena of beating, as long as we consider only the motion of the external air, is no exception from the common rule of undisturbed composition of the different sounds. You see that this machine of Mr. Wheatstone's, which possesses different vibrations, produces interference by adding, or by summing the vibrations together, after the common law. Therefore, this repose is produced by the common rule, that vibrations are added without disturbance. But it is another thing with the sensations of the ear; the sensation of two sounds have no two different phases. If we add one sensation to a second tone, we cannot expect to get the same by this addition; we should always expect that we should have the double sensation, but that is not the case. In the sensation of the ear there really is a difference; the sensations in the ear are not always summed together by the common law, and we cannot consider the sensation of two systems of waves like the sum of the sensation of the ear. The ear is a resounding body. Perhaps there are, in the interior of the ear, little elastic bodies, which resound differently for every pitch. This drawing [pointing to a diagram] represents parts of the internal ear. It is like the shell of a snail, vaulted, hollow, just separated by a wall, which is one-half osseous, and the other membranous. The nerves represented by the white stripes come to the osseous part, and then to the membranaceous part; there we find little elastic arches, called commonly the organs of concha. They are little elastic arches, of a very small size, which are connected with the nervous pipes. These little elastic arches spring if the membrane is shaken by the vibration of the air; and if we suppose that these elastic arches are tuned every one for a different pitch, then it would follow that, by every external sound, only one, or very few of these elastic bodies are put into vibration, and that only one or some nervous fibres are excited, the others remaining quiet, so that all the sounds of different pitch are also felt by different nervous pipes. Now, if we take another sounding body, the air of this little flask, and if I bring two tuning-forks before the mouth, you will hear the beatings, which show that the air in the interior of the flask is at first vibrating and then not—alternately vibrating and not vibrating. [The Professor excited the tuning forks, and held them before the mouth of the flask, when the alternate vibrations were distinctly heard.] Here the vibrations of the air are excited by the tuning forks; in the same way the vibration of the little elastic

bodies in the air must be excited by the external sounds. If two sounds come together which give interference, then the elastic bodies must repose, and the acoustic nerve cannot be excited. In this way we may explain that we can distinguish by our sensations the sounds of different pitch—indeed the sounds of different pitch seem to be the sensations of different nerves. We may explain further, that we separate the sensation of a complex sound into its single harmonics. This would be a real explanation of this curious fact, that we separate such a sound, which is not separated by the manner in which it is produced, not separated into single parts, but really by the complex sound as the sound of a string. All those particles must be put into vibrations which correspond to the fundamental sound, or the harmonics of the external sound; and we can give in this way an explanation of this curious analysis of sounds. Now, we will consider the beatings of two similar sounds if the difference of the sound becomes greater. We have had hitherto only small differences of the sound. You have heard the beatings quite plainly. Now, I can alter the pitch of the sound so that there shall exist great difference of pitch; then the beatings become very swift. This is nearly a difference of a semitone, and you hear the beatings very plainly. If you take a single tone also, you hear the beatings much more plainly. Then the number of the beatings is double—the natural *c* and the sharp *c*, the octave higher, is twice as fast. Here the beatings become almost distinct, and you will distinguish very well how the slow beatings pass into the swift beatings—[striking a lower note]; and therefore we have here the same phenomenon, only with great velocity—[striking lower notes]. Now this, I may say, is the real cause of the dissonance. If two sounds of nearly the same pitch are combined, they are not felt. They destroy each other sometimes, and strengthen each other at other times; so that they do not flow away in a continuous manner like the single sound, but they agree with each other, and disturb each other. Therefore, combining two distinct sounds by the single tone, we have beatings. Beatings, as I have explained to you, is an interrupted sound; and we have also an interrupted sensation in the ear. An interrupted sensation in the ear is disagreeable to the ear. It is the same with all other interrupted sensations. If you take a quivering light which falls upon the eye, you will be dazzled, and you cannot bear such a light a long time. You may compare it with scratchings on the skin. That is also a discontinuous sort of exciting the nerves of the skin. This same sort of disagreeableness exists for the ear, and makes it troubled; but by the sensation of two sounds which come to each other. I have given you by this the first phenomenon of dissonance. I would like to explain to you the dissonance of the harmonics, if you will allow me. I will show you by the siren that really interrupted sound gives quite the same impression to the ear. I can put into the siren here a little reed pipe, which gives a high tone. It is put into this box and the disc is turned. The holes here in the under side of the box are opened and closed alternately, so that the sound and the current of air can go out or is closed in. This interrupted sound which is then not a beating sound—not produced by the beating of two sounds, gives quite the same impression as a really beating sound, a sensation of dissonance, such as an interrupted sound. But we have also other dissonances of two sounds, which are not very near in their pitch: the dissonances of the impure octaves, and so on. In this case we must consider that nearly all musical instruments give harmonic sounds, and even these instruments which are of the best application in music, as the piano, the violin, the guitar, and sharp organ pipes. All these have harmonics of great intensity, and these harmonic sounds must all give beatings. We may show that in the organ. Here we have the sound of a stop pipe with feeble harmonics; but I may combine it with the higher sound, and thus give another quality of

sound. I connect it with the octave as it is connected in some of the registers of the organ which are called mixtures of the organ. Now, if I combine with this pure octave an impure octave, I make this beating: you have really in this case the beatings of these two sounds, but neither of these can be the harmonic, neither sound for instance in this reed pipe. You can hear the beatings and so on. If I take the fifth, then, these sounds have harmonics. If they are the harmonic sound of the lower and the harmonic sound of the higher, they will give no beating, but if they are not quite the same, then we shall have beatings. This is upon the fifth. You hear the beatings, they come swifter and swifter, the more the sound is altered. Now, if we suppose this theory that the difference of the pitch is felt by the different excitation of the little elastic sounds which are connected here with the ends of the nerves, we can calculate, for instance, from two sounds of a violin which are brought together, the amount of roughness which is produced by the intensity of beats of the different harmonics. We know the intensity of the different harmonics, and we can calculate by theory in what instances, the different little elastic solids will swing with each of these sounds and their harmonics, and we can calculate the intensity of the roughness, the intensity of the beatings which are produced by these two sounds.

Now, suppose that this drawing [pointing] represents the interior of an octave, the harmonic sounds, and that on the violin the sound is produced representing the fundamental sound of this octave, and another sound in any given interval of this octave from the first fundamental sound is produced at the same time. Then these little hills which are drawn above the curve represent the roughness of the intensity of the beatings which are produced by different harmonics of the two sounds. This lower curve represents the beatings produced by the fundamental sound, the black one the beatings produced by the first harmonic of the fundamental; the green the beatings of the second harmonic; the yellow the beatings of the third harmonic, and so on. Now, you see that here remain some valleys between these hills. These valleys correspond to such intervals where the roughness is a minimum, and you see the roughness is a minimum at first when the two sounds are in unison. The one is the octave of the sound. Then we have a deep valley which corresponds to the best consonants of the octave and the fifth. Then we have the other valley which corresponds to the fourth, one to the major third, minor third, the major sixth, and then a very imperfect consonance, the minor sixth. And here remains a place which corresponds nearly to the consonant interval which is not used in music—the natural seventh. Therefore you see that, calculating only by theory, the roughness of the beats we get quite completely, not only the places for the consonant intervals of the scale, but even the different degrees of the consonant intervals. Here the valley of the fifth comes down to the basis; that of the fourth not quite to the basis; that of the major third is still higher, and the minor third more so, and so on. And so we get the series of these consonantal intervals.

In this way we can give a complete account of the difference of consonance of these intervals. I must remark that as we have some qualities of sound without harmonics it seems that these would give no dissonances if they are not two sounds coming together. But in this case there is another phenomenon,—sounds of combination which I cannot describe here; they cannot be the subject of a public Lecture, because they are only heard by great attention and if one is quite undisturbed. It is a phenomenon which is not easily observed. I will only remark that for such cases where the harmonics are not very intense these combination sounds can also produce beatings, and that by those beatings of the combination sounds the dissonances and the consonances are determined in these cases where the harmonics are wanting. Whilst you will hear very easily the roughness of consonance, it is very different

if the quality of the sound is altered. I will alter the pitch of the octave. In the sound with strong harmonics you hear the beatings. Here the open pipe, they are there also perceptible, but not so sharp as before. In the stopped pipe they are of less intensity and so on. Now, these stopped pipes give, indeed, dissonances, but they are so feeble that the stopped pipes in the organ cannot be used for music in common. They are too soft, and have too small an amount of energy. The dissonances give energy; if the difference between consonances and dissonances is wanting, we feel a want of energy in the music, and, therefore, the stopped pipes can only be used exceptionally. And even the organ pipes have all too small an amount of harmonic sounds, and, therefore, if the intensity and energy of the organ is required, all these mixtures are used—that is, we combine artificially with other organ pipes some organ pipes which give the harmonic sounds of this pipe, so that we get the strong intensity of harmonics.

I shall conclude this Lecture by a more general consideration of the nature of that which impresses our mind as beautiful in the fine arts. The question which is illustrated in a very striking way by that which we have said on the theory of the harmonic. That there are laws to form every sort of beauty cannot be doubted, for we cannot alter any work of art arbitrarily without destroying its beauty. It may be a picture, statuary, a work of poetry, or a piece of music, but these laws are not given by our understanding. Some of them, indeed, can be expressed in the form of practical rules; but always the highest degrees of artistic beauty are those which are understood and described in the most difficult way. Philosophers, therefore, long ago have stated that there are laws of beauty—that beauty must agree with innate laws of our mind, that it reveals these laws: to the immediate perception of the senses, and that we feel its communication without being conscious of it. We may, indeed, understand and explain some parts of that beauty, some of its most striking features, but we would not be inclined to acknowledge as beautiful, in the artistic sense, a work which we know to be the effect of mere calculation and logical conclusions. Such a work always appears poor in beauty. We must feel that there is a larger stock of truth, nature and passion, in any work of art than we can derive by the mere speculation of the understanding; then such a work of art appears to us as infinitely rich; it appears as a revelation of that original harmony, consistency, and truthfulness, which belonged to the human mind, as it came from the hands of its Creator, before it was contaminated by egotism and stunted by the constraint of every-day life. This paradox has always puzzled philosophers.

We ought to feel the latent consistency and lawfulness of beauty without becoming really conscious of it, and without understanding it. Our present subject, however, gives a fine example of this process. We have in the present case only the most simple elementary rules of harmony, we have nothing to do with the higher rules of melody and musical composition. The consideration, however, which I have brought before you applies also to these elementary cases. We have seen that harmony is different from disharmony, by the beating of harmonic sounds. Now we have the sensation of these harmonic tones in our nervous apparatus; the existence of these sounds is level, also in the common use of the ear, or the difference we perceive between sounds of different qualities. But commonly, without performing philosophical experiments, we are not conscious of the existence of the harmonic tone in the sensation of our ear, and therefore of the phenomena depending on the existence of those tones, as, for instance, their beats are felt and an alteration of the quality of the sound commonly has a sort of roughness, we perceive very well that chords agreeing with the laws of consonance and agreeable to the ear are beautiful, and

different from dissonant chords, without being able to perceive the cause of this difference. Therefore we have here such a law of sensation as I have described before; we feel that two sounds coming together either agree or disagree, but we cannot say why they agree or disagree. In this way the general rule of artistic beauty is kept also in this case, where we have to do only with the more elementary part of music; for, of course, these our explanations are not sufficient to answer for the higher beauty of music, for its power and its softness, and you may expect that a long time will pass on before we shall be able to understand their mechanism. At present I think we must be content to have thrown only a glimpse into the first elementary questions of this beautiful subject.

NOTICES OF PATENTS.

145. *Preparation of Non-conducting Substances for the Deposition thereon of Metals by Electric Action.* B. PIFFARD, Caroline Villas, Kentish Town, London.

IN our second volume, p. 323, will be found a communication from Mr. Piffard on this subject. He has, it seems, further improved upon the process there given, and now takes out a patent for it. In carrying this invention into effect, the surface to which it is desired to impart a metallic coating is washed with a solution of nitrate of silver, in such a manner that a film of the solution adheres to the whole of the surface, which is then thoroughly dried, and afterwards exposed to the action of sulphuretted hydrogen gas. The result of this process is, that a conducting surface of metallic silver will be produced, which can then be treated by any of the known methods of obtaining the electro deposition of metals. If the surface under treatment will not retain a complete film of the solution of nitrate of silver, it should be previously washed with a thin solution of gum, or other suitable substance, and then dried, before applying the solution of nitrate of silver.

This is likely to be very successful, and will be a decided improvement upon the old methods of obtaining this result by the use of black lead or metallic powders.

163. *Cast Steel.* R. MUSHET, Coleford.

THIS invention consists in adding to steel, or to any mixture of materials which, when melted, produces cast steel, a mixture of granulated pig iron, cast or refined iron, and pulverised titanium ore, titaniferous iron ore, titanio acid, or oxide of titanium, and melting the said steel-producing materials, and the said mixture of granulated iron and pulverised titanium ore together in the melting-pot, in order to alloy the titanium contained in the said ore or oxide with the cast steel melted from the mixture of steel-producing materials, operated upon so as to produce thereby an improved quality of cast steel. And, secondly, in adding to steel, or to any mixture of materials which, when melted, produce cast steel, a mixture of granular iron and deoxidised ilmenite or compound ore of titanium and iron, and melting the said steel or steel-producing materials and the mixture of ore of titanium and iron and granular iron together in a melting pot, in order to improve the quality of the cast steel obtained.

175. *Telegraphic Cables.* J. CHATBERTON, Highbury Terrace, and W. SMITH, Pownall Road, Dalston.

FOR the purposes of this invention, in order that the gutta percha insulating coatings should not be subjected to heat in the process of manufacturing a cable—as has heretofore been the case when applying hot pitch, resin,

and other matters, together with or after the fibrous materials and wire coatings have been applied round the gutta percha coated wires—the patentees apply oxides or carbonates of lead, or other preparation of that or other metal, combined with tar, oil, or varnish, together with the fibrous materials, and externally of the insulating gutta percha coatings, whether wire be employed as well as fibrous materials to give strength to the cable or not. For these purposes the fibrous material used, whether made up in the form of tape, yarn, cord, or otherwise, is coated or saturated with the paint or composition above mentioned, and by preference in the act of applying such fibrous materials and whether such fibrous materials are wound spirally around or laid longitudinally over the surfaces of the gutta percha; and it is preferred to bind an uncoated tape exterior of the saturated coatings of fibre, in order that the cable may be at once coiled.

For obvious reasons, we think the introduction of any metallic compound in an insulating coating inadmissible; especially when, as in this case, we do not see what good end is gained by the addition.

106. *Iron and Steel.* W. LONGMAID, Inver, Galway.

THIS invention has for its object the alloying of iron and steel with minute quantities of gold and platinum, thereby greatly increasing the strength and otherwise improving the quality of the metals so treated. The gold and platinum are combined when in a melted state with the iron and steel when they are in a melted state, or in the progress of their manufacture. There is no doubt that the quality of steel and iron would be improved by this addition. Faraday proved that long ago; but we fancy that steel manufacturers would look twice at a sovereign before throwing it into the melting-pot. Mr. Longmaid need not fear infringements of this patent.

197. *Glass.* W. W. DOBESON and G. WARREN, Bill Quay Bottle Works, near Gateshead.

THESE improvements consist in using air under pressure under the gratings of the furnace, by which the draught through the fuel may be insured and rendered more constant and certain, notwithstanding the changes of weather. The air is forced into a closed ash-pit under the grating or fire-bars of the furnaces by means of a fan or any other suitable blowing apparatus.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Magnetic Chrome Oxide.—Geuther describes (*Annal. der Chem. und Pharm.* Bd. cxviii. s. 61) a process for procuring the magnetic chrome oxide (first obtained in the amorphous state by Wohler) in a crystalline form. He passes the vapour of acichloride of chromium evenly, and not too quickly, through a glass tube a foot and a-half long, heated in a combustion furnace. The ignited charcoal is placed so that it does not come into contact with the tube. When the tube has cooled, the inside is found to be covered with small glistening crystals, which, by their brilliant appearance and colour approaching to violet, may be easily distinguished and separated from the black crystals of the ordinary chrome oxide formed here and there in places where the heat has been very strong. The sparkling violet crystals are strongly magnetic, and must be crystals of the magnetic oxide. Care must be taken not to raise the heat too high, but the most crystals are formed when the tube is raised to the highest temperature allowable.

Geuther found that this magnetic oxide of chromium contains more oxygen than the green oxide. That prepared by the author lost 6.55; 5.88; 5.14 per cent. of oxygen when converted into the oxide Cr_2O_3 . If therefore, it is not considered as an independent oxide, it may be regarded as a compound of 2 atoms of chrome oxide and 1 atom of chromic acid. The crystallised magnetic oxide once formed is a very stable compound; but by long continued heating it may be converted into the green oxide, the crystals retaining their original form. The same change takes place quickly when the crystals are heated in a current of hydrogen. In the amorphous state this oxide is a black powder insoluble in hydrochloric, nitric, and nitro-hydrochloric acids, or even in a mixture of fluoric and nitric acids. By boiling in a strong solution of the fixed alkalis it is slowly converted into chrome oxide and chromic acid, and quickly undergoes the same

change when fused with hydrates of the alkalis. The sp. gr. at 10° is close upon 4; it stands, therefore, in this respect between that of chromic acid 2.63, and that of the crystallised green oxide 5.21. The crystals appear to be prisms with a rhombic base. Some magnetic oxide appears to be formed when pure chromic acid is heated alone or in a current of oxygen.

Nitro-iodic Acid.—The yellow body obtained when iodide is treated with mono hydrated nitric acid, Kaemmerer regards (*Journ. für prakt. Chemie*, Bd. lxxxiii. s. 65) as nitro-iodic acid, or iodic acid in which one equivalent of oxygen is replaced by one atom of nitric oxide. The formula therefore is (IO_4NO_2) . The substance is most easily prepared by rubbing iodine in fine powder with a mixture of equal parts of ordinary fuming nitric acid and strong sulphuric acid. It is a very unstable compound. When dried over lime under a glass bell it decomposes, giving off nitric oxide gas. Water destroys it. A very small quantity brought in contact with absolute alcohol, ether or acetic ether sets fire to those bodies and gives off thick clouds of iodine vapour. Exposed to the air at a moderate temperature it quickly breaks up into I , IO_3 , and NO_2 , but at a very low temperature and in a dry atmosphere it may remain unchanged for twenty-four hours. Concentrated sulphuric acid dissolves it slowly without decomposition. It is precipitated from the solution, however, when the sides of the vessel are rubbed hard with a glass rod, or when strong nitric acid is added.

Double Hyposulphates.—Dr. Kraut describes (*Archiv. der Pharm.*, Bd. clvi. s. 129) crystals of double salt $\text{BaS}_2\text{O}_8\text{Na}_2\text{O}_8 + 4\text{Aq.}$ obtained by the spontaneous evaporation of a solution containing equivalent weights of the two salts. Crystals of the baryta salt are obtained first, then some of the soda salt, and lastly, large transparent crystals of the double salt. The crystals are permanent in the air. They have rounded angles and convex surfaces.

Another double salt $\text{Ag}_2\text{S}_2\text{O}_8\text{Na}_2\text{O}_8 + 4\text{Aq.}$ is obtained in the first crystallisation of a solution, containing equivalent weights of the two salts. The crystals appear to be isomorphous with the soda and silver salts. They effloresce over oil of vitriol, but not in the air. The author could not form double salts with the hypsulphates of many of the metals.

II. ORGANIC CHEMISTRY.

Amount of Theine in Paraguay Tea.—Rammelsberg found (*Bericht. der Akad. der Wissenschaft zu Berlin*, 1861, s. 263) that benzole easily extracted the theine from Maté, or Paraguay tea. In this way he obtained 0.44 per cent., a much larger proportion than Dr. Stenhouse extracted.

Ether Formed by Fermentation.—Leuchs says (*Chem. Centralblatt*, No. 25, 1861, s. 385) that raisins, from which the greater part of the sugar has been extracted by boiling, made into balls, laid under a glass bell, and kept at 18°C . form ether, which is also produced when cotton wool, moistened with a mixture of sugar, spirit of wine and water, is placed under the same circumstances. The author says that ether is always formed when spirit of wine, sugar and water are simultaneously present in porous bodies.

Influence of Sulphur on Fermentation.—When finely-powdered sulphur is placed in grape juice, Leuchs says the fermentation goes on as usual with the formation at the same time of a good deal of sulphuretted hydrogen. If the must is not too much diluted with water, there is a smell, and even taste resembling that of garlic or onions, but when much diluted the smell is more like that of liver of sulphur. The sugar appears to be decomposed but slowly, for the fluid remains sweet a long time. Leuchs suggests that mineral waters, containing sul-

phuretted hydrogen and carbonic acid, may be prepared by fermenting with a little sulphur. Grapes which have been dusted over with sulphur to cure the disease, the author says, give wine that smells of sulphur, but loses the smell in six months, in consequence of the oxidation of the sulphur. Powdered sulphur added to a solution of grape sugar excited no fermentation in the first eight days. Afterwards the fluid became cloudy, and sulphuretted hydrogen was evolved. The fluid passed through filtering paper with great difficulty, and gum appeared to have been formed. (*Ibid.* s. 387.)

MISCELLANEOUS.

The Urine of *Omnivora* reduces ferricyanide of potassium to ferrocyanide, which can be shown by the addition of an iron or copper salt. It is occasioned by the uric acid in solution.—Dr. L. C. Levoir.

The Bessemer Process of Making Steel.—Hematite pig-iron, smelted with coke and hot-blast, has chiefly been used. The metal is melted in a reverberatory furnace, and is then run into a founder's ladle, and from thence it is transferred to the vessel in which its conversion into steel is to be effected. It is made of stout plate iron, and lined with a powdered argillaceous stone found in this neighbourhood below the coal, and known as ganister. The converting vessel is mounted on axes, which rest on stout iron standards, and by means of a wheel and handle it may be turned into any required position. There is an opening at the top for the inlet and pouring out of the metal, and at the lowest part are inserted seven fire-clay tuyeres, each having five openings in them; these openings communicate at one end with the interior of the vessel, and at the other end with a box called the tuyere box, into which a current of air from a suitable blast engine is conveyed under a pressure of about 14lb. to the square inch, a pressure more than sufficient to prevent the fluid metal from entering the tuyeres. Before commencing the first operation, the interior of the vessel is heated by coke, a blast through the tuyeres being used to urge the fire. When sufficiently heated, the vessel is turned upside down, and all the unburned coke is shaken out. The molten pig iron is then run in from the ladle before referred to; the vessel, during the pouring in of the iron, is kept in such a position that the orifices of the tuyeres are at a higher level than the surface of the metal. When all the iron has run in, the blast is turned on, and the vessel quickly moved round. The air then rushes upwards into fluid metal from each of the thirty-five small orifices of the tuyeres, producing a most violent agitation of the whole mass. The silicium, always present in greater or less quantities in pig iron, is first attacked. It unites readily with the oxygen of the air, producing silicic acid, at the same time a small portion of the iron undergoes oxydation, hence a fluid silicate of the oxide of iron is formed, a little carbon being simultaneously eliminated. The heat is thus gradually increased until nearly the whole of the silicium is oxydised; this generally takes place in about twelve minutes from the commencement of the process. The carbon now begins to unite more freely with the oxygen of the air, producing at first a small flame, which rapidly increases, and in about three more minutes from its first appearance we have a most intense combustion going on: the metal rises higher and higher in the vessel, sometimes occupying more than double its former space. The frothy liquid now presents an enormous surface to the action of the oxygen of the air, which unites rapidly with the carbon contained in the crude iron, and produces a most intense combustion, the whole, in fact, being a perfect mixture of metal and fire. The carbon is

now eliminated so rapidly as to produce a series of harmless explosions, throwing out the fluid slags in great quantities, while the union of the gases is so perfect that a voluminous white flame rushes from the mouth of the vessel, illuminating the whole building, and indicating to the practised eye the precise condition of the metal inside. The workman may thus leave off whenever the number of minutes he has been blowing and the appearance of the flame indicate the required quality of the metal. This is the mode preferred in working the process in Sweden. But here we prefer to blow the metal until the flame suddenly drops, which it does just on the approach of the metal to the condition of malleable iron: a small quantity of charcoal pig iron, containing a known quantity of carbon, is then added, and steel is produced of any desired degree of carburization, the process having occupied about twenty-eight minutes from the commencement. The vessel is then turned, and the fluid steel is run into the casting ladle, which is provided with a plug rod covered with loam: the rod passes over the top of the ladle, and works in guides on the outside of it, so that, by means of a lever handle, the workmen may move it up and down as desired. The lower part of the plug, which occupies the interior of the ladle, has fitted to its lower end a fire-clay cone, which rests in a seating of the same material let into the bottom of the ladle, thus forming a cone valve, by means of which the fluid steel is run into different sized moulds, as may be required, the stream of fluid steel being prevented by the valve plug from flowing during the movement of the casting ladle from one mould to another. By tapping the metal from below, no scoria or other extraneous floating matters are allowed to pass into the mould.

When in a closed Funnel a jet of water enters with pressure in the direction of the tangent at the largest circumference, and coal-gas enters in the direction of the axis, the gas can be lighted amidst the jet of water which revolves downwards.—Dr. L. C. Levoir.

Copper Smelting.—*The Ontonagon* (Lake Superior) *Miner* states that the representatives of the French company have been making investigations among the mines of the Ontonagon district in relation to the establishment of smelting works, and that the result of their investigations will undoubtedly be the early erection of such works. The fuel used will be wood. In June, the Isle Royale Mine, turned out 65 tons of copper, the Franklin 80, the Pewabic 85, the Quincy 140, and the Huron, Hancock, and Portage 22 tons, making an aggregate of 396 for the month.

ANSWERS TO CORRESPONDENTS.

* All Editorial Communications are to be addressed to the EDITOR; and Advertisements and Business Communications to the PUBLISHER at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

* In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Coke.—A small square box, containing two lumps of coke, was delivered by a carrier, carriage-paid, at the Editor's private address, last week. There was no name of the sender, or anything else on it, to show whence it came; and no letter has since been received which in any way refers to it.

J. A. Tring.—The metal is deposited on the pens by the electrolytic process, and subsequently polished by friction. The most uniformly successful electrolytic solutions consist of double cyanides of the metal to be deposited, with cyanide of potassium.

Nemo.—1. Mr. Leslie's address is Conduit Street, Regent Street. 2. The first patent is tenable unless the other party has previously published the principle of it. Private knowledge of it goes for nothing.

A Poor Chemist's favourable opinion has been received by the Editor with much pleasure.

THE CHEMICAL NEWS.

VOL. IV. No. 91.—August 31, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Colour-tests for Strychnia and the Diagnosis of the Alkaloids, by WILLIAM A. GUY, M.B. Cantab. Fellow of the College, and Professor of Forensic Medicine, King's College, London.

(Continued from vol. iii. p. 303.)

THE last of the four questions proposed for solution in my first communication still remains to be discussed. It relates to the diagnosis of the alkaloids, and was expressed in the following terms:—Is it possible by means of the colour-tests, or by any simple modification of them, to distinguish the alkaloids from each other?

Before proceeding to examine this question I must briefly refer to what I have already stated respecting the colour-tests. These tests, as commonly understood, are compound tests, consisting first of the reaction of the alkaloid with sulphuric acid, and then of the reaction of the peroxides of lead and manganese, the bichromate of potash, the ferricyanide of potassium, and the permanganate of potash, with the mixture of the alkaloid and sulphuric acid.

The sulphuric acid produces in strychnia no change of colour. Hence the acid itself becomes a test of no mean value. It serves, as I shall point out more particularly presently, to distinguish strychnia from a considerable number of the alkaloids, and also from several substances which give with sulphuric acid alone coloured reactions, some of which reactions with the acid alone bear a certain resemblance to those of strychnia with sulphuric acid *plus* the bichromate of potash, ferricyanide of potassium, permanganate of potash, peroxide of lead, or peroxide of manganese. In order to distinguish strychnia from other alkaloids, and from the substances to which I have just referred, it is essential that the sulphuric acid should be first applied to, and well mixed with, the strychnia, and that the absence of colour having been noted, the reagents that develop the colour should be in their turn applied. In all that I have said on the subject of the colour-tests for strychnia, and in what I have yet to say, I assume this mode of procedure to be strictly observed; and I shall continue to speak of these reagents as the colour-producing tests.

I have hitherto assumed that the sulphuric acid is applied cold; but I shall presently point out that we may greatly add to the value of this constituent portion of the colour-tests by first warming and then heating the acid solution. A very slight rise of temperature serves to develop very beautiful and characteristic colours in some of the alkaloids, while it does not change the colour of strychnia. A further rise of temperature to the point of causing the mixture to give off vapour,

develops colour in strychnia also, and deepens or changes the tints already imparted to the alkaloids previously affected by warming the acid mixture.

The colour imparted to a solution of strychnia in sulphuric acid by raising it to a temperature at which it gives off vapour is not strongly marked. It is a faint yellow or light greenish-brown, differing somewhat in depth of tint with different specimens of strychnia treated in all respects exactly alike. If the acid solution is allowed to cool it no longer acts characteristically with the bichromate of potash or the other tests. Their action is wholly destroyed or greatly impaired. Hence in applying the colour-tests for strychnia, we must use concentrated pure sulphuric acid, and use it cold.

So much for the first part of the colour-tests. We add to the alkaloid under examination sulphuric acid in small quantity—pure, strong, and cold; and it undergoes no change of colour. The alkaloid, therefore, whatever it may be, belongs to the class of which strychnia is one.

To this cold acid solution of the alkaloid we add a minute fragment of bichromate of potash, ferricyanide of potassium, permanganate of potash, peroxide of lead, or peroxide of manganese. The result is the remarkable development of successive transient, or short-lived, colours already described.

The negative reaction of strong cold sulphuric acid on strychnia, followed by the effect of heat on the acid mixture, and this by the peculiar colours produced by the application of the colour-developing substances to the cold acid mixture, constitute a series of phenomena which afford fair promise of proving the means of a successful diagnosis of the alkaloids.

To this work of distinction I now address myself, and in order to prepare the way more completely for the work of tabular analysis towards which the details given in my former communications have been tending, I must again revert to the question whether the action of the colour-tests on strychnia is, or is not, characteristic, and therefore, diagnostic.

This is a question which must have suggested itself to every chemist engaged in medico-legal inquiries as of the utmost practical importance, and one chemist (Mr. Thomas E. Jenkins) having been employed to investigate a case of suspected poisoning, in which the colour-tests gave indications of the presence of strychnia, very properly put the question to the test of experiment, by applying to a variety of active principles, including most of the alkaloids, first, colourless concentrated sulphuric acid, and then a fragment of a crystal of bichromate of potash. The experiments, which were carefully performed, and appear to have been strictly comparable one with another, embraced no less than fifty alkaloids and active principles, derived from the animal as well as the vegetable kingdom, and among them, urea and uric acid, and cantharidine. More than half of these substances differed from strychnia in yielding colour when treated with sulphuric acid. The smaller half resembled strychnia in this respect. But not one of the whole

¹ Substance of part of the Croonian Lectures for 1861, delivered at the Royal College of Physicians; from the *Pharmaceutical Journal*.

fifty gave with the bichromate of potash the characteristic coloured reactions of strychnia. Feeling that my time would not be wasted in repeating his experiments, and, if possible, extending them to substances not included in his list, I possessed myself (partly by the kind assistance of Mr. Morson) of all the alkaloids and similar active principles which could be obtained, and tested them in the same way. To Mr. Jenkins' list, some of which I was not able to procure, I succeeded in adding as many as sixteen new substances. None of these gave the characteristic coloured reactions of strychnia, nor any succession of colours any way resembling them, so that I am now in a condition to assert that strychnia stands alone among sixty-six analogous compounds in the reactions which it gives with sulphuric acid followed by the bichromate of potash.

Mr. Jenkins (as will be seen in the table published by him in the *CHEMICAL NEWS* for October 6, 1860) arranges his reactions in two columns. The first column displays the effect produced by strong sulphuric acid; the second, the changes of colour caused by the addition to the acid solution of the bichromate of potash.

Now this table affords an excellent illustration of the absence of method and logical arrangement. The substances operated on evidently took their places as they chanced to come to hand. Strychnia itself has to be sought out; and substances which give coloured reactions with sulphuric acid, find themselves in contact with others that give a negative result.

And yet the table seems to court the attention of lovers of method and logical order. It is almost impossible to keep one's hands off it. At least, one would like to place the substances which are not coloured by sulphuric acid by themselves, and those that are coloured also by themselves. I have undertaken this work of tabulation, and, on inspecting the result, am seized with the same desire to resume the work of arrangement. In both groups there are substances which yield with bichromate of potash the same colours. Why should not these similar reactions be bracketed together? This, accordingly, I have carried into effect, and the result is a splitting up of the fifty substances into several groups of such moderate dimensions, that a man given to tabular analysis can scarcely resist the additional temptation to try whether some modification of the tests themselves, or some additional tests, or both together, may not lead to a successful separation and elimination of each and all the substances contained in the table.² I now proceed to lay before you in a tabular form the results of a very laborious experimental attempt to distinguish some of the principal alkaloids and active principles, whether derived from the vegetable or animal kingdom, from each other.

As the first object which I had in view was to distinguish the poisonous alkaloids and analogous active principles from each other, these substances are of course admitted into the tables; but I have added to these the active principles of many of our aperient medicines and common articles of diet; and have ex-

cluded only such of those substances as were so strongly characterised by colour or odour, as not to be properly grouped with the colourless, or faintly-coloured, and inodorous alkaloids and active principles.³ The table, divided for convenience into two, consists, as it is, of as many as thirty-five different substances, closely resembling each other in physical properties and chemical composition, and offering collectively a very difficult subject for tabular analysis. The tables, as you have them before you, are the result of a long series of experiments, and were only made to assume their present form after a great many experimental groupings and transpositions.

The first object which I had in view was to find some simple test which would divide the whole body of active principles comprised in the two tables into two principal groups. Concentrated sulphuric acid, as a constituent of the strychnia colour-tests, was obviously well adapted to this purpose. It has the effect of dissolving the alkaloids and active principles without change of colour in the case of one considerable group (Table I.), and with change of colour in the case of another considerable group (Table II.). The first group (Table I.) comprises the majority of the active poisonous principles—strychnia, brucia, morphia; atropine, picrotoxia, aconitina; and the animal principle cantharadine. With these and several other alkaloids and active principles, some of which are very harmless ones, concentrated sulphuric acid either produces no change of colour, or a faint yellow, straw, or buff tint.⁴ I speak of cold concentrated sulphuric acid, applied as in the preliminary to the colour-tests for strychnia.

The next object which I had in view was to subdivide these two large groups (Tables I. and II.) each into two or more smaller groups by some second test, which might also, perchance, produce in some members of the two groups characteristic reactions, so as to eliminate or separate them at once. For this purpose I tried the effect of warming the acid solution of the alkaloids by passing the porcelain slab through the flame of the spirit lamp, so as to raise the temperature of the liquid to a point short of that at which it gives off vapour. This subsidiary test answered its purpose completely; the group of substances in Table II. which had already given colours, more or less characteristic, with the cold acid, underwent further changes of colour more or less peculiar; while the group in Table I. which had undergone no change with the cold acid, became subdivided into two leading groups, of which one continued without colour, and the other underwent changes of colour more or less characteristic. In the instances of meconine and of aconitina, the colours developed proved to be peculiar to these substances, so as to lead at once to their elimination from the rest.

By raising still further the temperature of the acid solutions to a point at which vapour was given off, a further separation into distinct groups or classes was

³ To this statement it will be seen that there are one or two exceptions, such as naphthaline, which, though colourless, has the odour of tar.

² In the lectures given at the College of Physicians, Mr. Jenkins's original table, and the two tabular arrangements alluded to in the text, were sent round. These tables were the more freely used as illustrations of a want of logical arrangement, as the author evidently did not aim at diagnosis, but only at the distinct ascertainment of the peculiar and characteristic reactions of strychnia. The remarks in the text were not, therefore, intended in any respect as a censure of Mr. Jenkins for not adopting an arrangement which, for his purpose, was unnecessary. I may add, that his table comprises several substances which will not be found in the tables I am about to submit. I mean such substances as the kinic and kinovic acids, and such animal products as urea and uric acid.

⁴ I ought to state in this place that some of the alkaloids are very sensitive to heat, so that a very slight rise of temperature is followed by a decided development of colour. Hence it is possible that experiments made in a cold room in winter may yield results differing somewhat from the same experiments made in a warm room in the height of summer. It must also be borne in mind that sulphuric acid, if not free from nitric acid, may impart to some of the alkaloids a tint of rose, yellow, or buff, sufficiently deep to justify their removal from Table I. to Table II. It may be well, therefore, to state that the experiments on which the tables are founded were made in the winter, in a room with a fire, but in the morning, before the temperature of the room had been raised to a point approaching summer-heat; and that the acid employed was free from nitric acid.

found to take place. The six substances which stand first in order in Table I. still remained colourless, while the remainder assumed tints more or less characteristic. Esculine and atropine; picrotoxia, santonine, and narcotine; amygdaline and naphthaline, formed themselves into three distinct groups; while strychnia, brucia, and morphia gave indications of colour less distinct and characteristic.

By this triple test of sulphuric acid—cold, warmed, and heated—the active principles contained in this division (Table I.) have been either eliminated, or split up into manageable groups, awaiting the application of further tests. It seemed natural to select as the next test in order nitric acid—a known characteristic test of brucia and morphia. By applying this test to the several members of the table in succession, codia was isolated from the group of six to which it belonged by the distinct yellow colour assumed by the acid solution. Emetine was, in like manner, isolated from the other members of the same group of six, by yielding with the acid a yellow-brown colour. Atropine, again, was distinguished from esculine by giving a negative result, while esculine assumed a distinct yellow colour. In the same way narcotine was detached from its group of three, and naphthaline from its group of two. Again, morphia was distinguished by the rich orange hue given by the acid, together with the red fumes of nitrous acid; and brucia was effectually distinguished from strychnia by the intense red of the former contrasting with the faint tinge of red imparted to ordinary specimens of the latter. For the next eliminating test I have selected sulphuric acid followed by a solution of permanganate of potash, in the proportion of 10 grains of the salt to 3j. of water. The effect of this test on strychnia was to develop its characteristic colours, strongly contrasted with the altogether different colours given with brucia, and still more with the brown colour imparted to morphia, followed by the bleaching of the liquid. This same test divided the somewhat unmanageable group of four at the top of the table (cantharadine and asparagine, and caffeine and cinchonine) into two small groups of two each. In the first two the immediate effect of the permanganate was a red-brown colour; in the second, a pink. Picrotoxia and santonine gave the same colour (pink) and remained undistinguished. The last and ultimate work of elimination was effected by means of heat applied to the active principle in its solid state. Cantharadine was found to be wholly dissipated by the heat of the spirit lamp, while asparagine gave a bulky carbonaceous deposit. And caffeine was found to present the same difference when compared with cinchonine. Lastly, picrotoxia was found to be distinguished from santonine by the bulky carbonaceous residue with the first, and the scanty deposit of carbon with the second.

Having by this succession of tests obtained a clue to the active principle with which we have been dealing, we should proceed to identify the substance indicated by the table, through its own characteristic tests.

In the second division of the one large table of elimination, or that which comprises active principles coloured by contact with cold sulphuric acid (Table II.), the same succession of tests is employed. Cold concentrated sulphuric acid at once separates this group of seventeen into eight smaller groups of one, two, or six; and the subsequent warming and heating of the coloured acid solutions occasions such marked differences of colour as to nearly complete the work of elimination. But I have added columns showing the effect of nitric acid, and of

the solution of permanganate of potash. The application of heat to the alkaloids themselves did not prove necessary to the work of elimination.

I submit these tables primarily as specimens of Tables of Elimination; but also incidentally as tables which may prove serviceable to the chemist. I am not certain that they constitute the best aid which could be devised to the diagnosis of the alkaloids. I thought that they might, perhaps, admit of being simplified by adding to the three columns headed "sulphuric acid" a fourth, showing the deposit of carbon resulting from the continued application of heat to the acid solution of the alkaloid. I tried this reaction in the case of fourteen alkaloids and active principles, comprising all the more active poisons of this class, together with the less important principles, emetine and meconine, and found the alkaloids to differ from each other in the amount of carbonaceous deposit. With strychnia, aconitina, and veratria, for instance, the deposit of carbon was less abundant than with brucia, morphia, atropia, and the other poisonous alkaloids. But the difference was not such as to justify me in using it as a diagnostic property. So also with the direct application of heat to the alkaloids themselves. Strychnia, morphia, atropia, cantharadine, meconine, picrotoxia, and delphinia, after melting, deposited but a scanty carbonaceous ash; while emetine, aconitina, and digitaline yielded an abundant ash; and brucia, elaterine, veratria, and solanine yielded an ash intermediate in quantity. This test, again, though fairly applicable to the few cases in Table I., did not seem admissible as a diagnostic on a larger scale. Indeed, the tables, though carefully compiled and based on carefully-conducted experiments, are open to the obvious objection that, with different specimens and different quantities of the alkaloids, and with different specimens of sulphuric acid, we may obtain differences of tint, and more or less ready development of colour under increase of temperature. The majority of the reactions, however, will, I believe, be found constant for all specimens of fair average purity. One

Of the two tables, Table I. affords the best illustration of a table of elimination. For the sake of brevity, and for other reasons already explained, the figures 1, 2, 3, are added to the words describing the colours developed by the tests. These figures indicate different degrees of intensity. In comparing strychnia with brucia, for instance, the figure (1) attached to the word "yellow" opposite strychnia in the third column means a faint yellow colour, less in degree than that indicated by the figure (2) opposite brucia in the same column. So the word "brown" with the annex 3 in the same column opposite esculina and atropine indicates an intense brown colour; the words red 3 and orange 3 in the column headed nitric acid indicate intense red and orange respectively.

On some Combinations of Selenium Analogous to Sulphides, by M. H. UELSMANN.

Selenide of Arsenic, AsSe_3 , deposits itself as a brilliant dark brown powder, when seleniuretted hydrogen is passed into a solution of arsenious acid, slightly acidulated with hydrochloric acid. The seleniuretted hydrogen was prepared by M. Wöhler's process, which consists in making pure, dry, and warm hydrogen act on selenium. Selenide of arsenic melts at 200° , forming a black liquid, which, when cold, forms an amorphous mass, with conchoidal fracture. It is soluble in alkalies, and colours the solution red-brown; nitric acid also dissolves it.

By melting together equal equivalents of arsenic and selenium, a shining, black, amorphous mass, with conchoidal fracture, is formed, soluble in caustic soda by the aid of heat, and yielding a brown-red liquid, and depositing itself from this solution in brilliant, bronze-coloured scales. This body appears to be AsSe_3 .

Selenide of Antimony, SbSe_3 , obtained by precipitating a solution of tartar emetic by seleniuretted

hydrogen, it is a black powder, which, when heated to 146° , suddenly becomes gray. At a red heat it melts into a black liquid, which becomes a granular, crystalline mass. It is soluble by heating in caustic potash, giving it a yellow-brown colour.

Selenide of Tin.—Protoselenide, SnSe , is formed by precipitating a solution of protochloride of tin by seleniuretted hydrogen. It is a brown powder, black when dry, easily soluble in caustic alkalies and in alkaline sulphides, and is neither fusible nor decomposable when heated in a glass tube in an atmosphere of hydrogen.

The same combination is produced with incandescence by heating three parts of tin and four of selenium in a current of carbonic acid. It forms a gray, crystalline, readily-clearable mass, with metallic lustre.

Biselenide of Tin, SnSe_2 , obtained by means of bichloride of tin and seleniuretted hydrogen, is a dark, yellow-orange coloured powder, clear red-brown when dry. By heating in a current by hydrogen, this selenide loses half its selenium and becomes protoselenide. It is soluble in caustic and sulphuretted alkalies; the solutions deposit selenium when exposed to the air.

Selenide of Tungsten, WSe_3 .—A solution of tungstate of soda, saturated with seleniuretted hydrogen, has a brown-red colour. Diluted sulphuric acid precipitates black selenide of tungsten from it, with disengagement of seleniuretted hydrogen. Selenide of tungsten is soluble in caustic alkalies and in alkaline sulphides and selenides.

Selenide of Molybdenum is similarly produced, but it is impure through the presence of a bluish-gray combination.

Selenide of Bismuth, BiSe_3 , is black. It forms, when melted, a metallic-looking button. It is precipitated when a limpid solution of bismuth, with as little acid as possible, is treated by seleniuretted hydrogen. It is soluble in nitric acid, but resists caustic alkalies and alkaline sulphides.

Selenide of Gold, AuSe_3 , is produced by passing seleniuretted hydrogen into chloride of gold in the dark. It is black, and decomposable by heat and by nitric acid.

Selenide of Mercury.—The selenide HgSe is obtained by direct combination, whatever proportions are employed. The combination is effected with hissing sound. At a high temperature the selenide is gaseous, and condenses into brilliant crystals, of a steel-gray colour, with black powder.

By directing a current of seleniuretted hydrogen through a solution of bichloride of mercury, a white precipitate is first produced, containing $2\text{HgSe} + \text{HgCl}$. Nitric acid does not attack this combination. Caustic soda transforms it into $2\text{HgSe} + \text{HgO}$.

Selenide of Cadmium, CdSe , prepared by chloride of cadmium and seleniuretted hydrogen, forms a brown powder, decomposable by hydrochloric acid, with disengagement of seleniuretted hydrogen.

Selenide of Sodium.—Sodium and selenium unite with ignition when heated, forming colourless selenide of sodium. By passing seleniuretted hydrogen into a solution of caustic soda, it assumes the form of a crystalline mass. When the mass is heated, while a current of hydrogen traverses it, the selenide dissolves, and on cooling deposits long, flat crystals. It becomes red and hot in the air.—*Annalen der Chemie und Pharmacie*, vol. cxvi., p. 122.

⁵ In the lectures at the College of Physicians a table was used which showed the colours actually produced by the action of the several re-agents on these poisonous alkaloids and active principles.

TECHNICAL CHEMISTRY.

On the Occurrence of Soluble Compounds of Copper, Lead, and Tin in Newly-distilled Alcoholic Spirits, by Dr. A. A. HAYES.

IN an article discussing the question of the existence of poisonous bodies, especially strychnine, in the spirits produced from grain, which has been so frequently agitated by the public journals during the past few years, Dr. A. A. Hayes expresses his conviction that no good reason can be found for the statements affirming the existence of such substances, which have been made by the newspapers; and remarks that his opinion is founded not only upon an extensive series of analytical observations, but is supported by the testimony of the parties most likely to know of such adulteration if it were really made, none of whom had ever met with a case at the places of manufacture which would lead even to an inference that any deleterious body had been purposely added to the distilled spirits.

But while dismissing this bugbear, Dr. Hayes calls attention to another source of danger which may be of importance. "Newly-distilled spirits, of the most common kind often contain salts of copper, of lead, or tin derived from the condensers, in which the vapours are reduced to a fluid form. The quantity of copper salt contained in the bulk usually taken at a draught, is sufficient to produce the minor effects of metallic poisoning; the cumulative character of these poisons may even lead to fatal consequences. With a knowledge of the fact now stated, instead of resting on a supposition of the existence of an organic poison in the spirit, which may have caused sickness, the physician should notice the symptoms of metallic poisoning in persons addicted to the habit of consuming newly-distilled spirits, and interpose his aid in preventing the fatal termination of vicious indulgence."

The author goes on to remark, that since he first became aware of the frequent occurrence of these metallic salts in recently manufactured spirits, he has made investigations which "prove that as all spirits at one time were new, so with few exceptions—arising from peculiar rectifications—most spirits have been, or are, more or less, contaminated by metallic compounds. Old or more matured spirits have generally lost every particle of the salts once held in solution. Changes in the organic solvent have caused the deposition of the metallic compound accompanied by the organic matter from obvious sources and in such spirits the metallic oxide is always found—if it has been present—in the dark coloured matter which has been deposited at the bottom of a cask at rest. This dark deposit has the appearance of, and has been mistaken for, charcoal, detached from the charcoal staves of the casks in which the spirits have been stored. Of this dark deposit every sample has, on examination, afforded abundance of copper, copper and tin, or copper and lead, even when taken from the finer qualities of foreign spirits. Observations have been made on the nature of this change from a soluble to an insoluble state. Samples of new spirits have been kept in glass vessels until the whole metallic salt has fallen in dark flocks, leaving the clear fluid free from any metallic compound and perfectly pure. It appears, therefore, that matured spirits lose their poisonous impregnation during the time necessary to adapt them for use as beverages, and that while the clear, transparent fluid contains no metallic impregna-

tion, a turbid though ripened spirit may prove deleterious, through its suspended metallic compounds. In order to avoid the poisonous effects of these salts, perfectly well-ripened and clear spirits only should be used in the preparation of medicines, and when ordered as restoratives, no new or turbid alcoholic fluids should be allowed to enter the hospital or room of the patient."

Dr. Hayes explains the origin of these salts as being connected with the production of acids, as well as alcohol in the fermenting vats. "When the wort is subjected to heat in the still, acetic, butyric and other acids rise with the vapour of alcohol, and pass into the condenser, now most commonly made of copper, with masses of solder containing lead. At the instant of condensation, these acids exert a power of corrosion on the metals quite unsuspected, and the salts formed dissolve in the spirit. Where condensers of pure tin are used, no copper salt is formed, and a little tin salt takes place. With the vapour of dilute alcohol some vesicular vapour of the wort is carried forward, and the dextrine which can be found in the spirit; another portion of soluble organic matter is abstracted from the wood of the cask, and this is often tannic acid. In the subsequent chemical changes these organic compounds unite with the salts, and fall in the form of a sub-granular dark matter seen in colourless spirits of all kinds. In detecting the metals held in solution, the extract obtained, after evaporating the spirit, must be destroyed, as usual in toxicological testing, and an acid solution of the oxide obtained; or the extract may at once be mixed with carbonate of soda, and the metal reduced by the blowpipe flame. When the deposit is the subject of trial the metal or metals appear on fluxing with carbonate of soda, in the inner flame produced by the blowpipe, on charcoal.—*Boston Medical and Surgical Journal*, lxiii. 169.

PHARMACY, TOXICOLOGY, &c.

On Liquor Ferri Iodidi, by W. J. M. GORDON, Cincinnati.

NEWLY-prepared syrup of iodide of iron, according to the United States Pharmacopœia, is a transparent liquor of a pale green colour, but frequently becomes a dark red. If exposed to the direct light of the sun, it is restored to its original transparency and colour. The same change will take place if exposed to the indirect light, but requires a much longer time. The loss of colour by the action of light distinguishes the syrup from a watery solution of the iodide of iron, which, if exposed to light, undergoes continual decomposition, becoming darker and darker. The inference is very clear, that the deoxidising influence of the sugar, which is so well known, protracts the decomposition; but the darkening of the syrup continues if the light is excluded, and to the light must be attributed a great influence on the changes going on in the syrup. To ascertain what these changes are, the following experiments have been made:—

1. A dark syrup was filtered; the filtered liquid was clear, of a reddish-brown colour, and contained free iodine, as a test with starch clearly showed. On the filter remained a deposit, which, after being well washed, dried, and heated, smelled strongly of iodine, and left oxide of iron. The solution of this deposit in nitric acid, after an addition of starch, became blue.

2. Some of the dark syrup was exposed to the direct

light of the sun, filtered after it had assumed a light green colour, and the well-washed deposit on the filter was found to be oxide of iron, entirely free from iodine, and in the syrup there was no longer any free iodine, as a test of starch showed.

3. Fifteen grains of iodide of iron and one ounce of water were put in two white bottles; these were exposed to the sunlight; in both of them the liquid soon became turbid, and assumed a red colour, caused by free iodine. To one of the bottles was then added a small quantity of sugar, and its contents became almost immediately nearly colourless and clear, depositing sediment of oxide of iron, while the liquid in the other bottle was constantly becoming darker, and seemed to be entirely decomposed.

From these experiments, the following conclusions have been arrived at. In the dark syrup a combination of iodide of iron is suspended, and free iodine dissolved in it. In the syrup decolorised by the light there is no longer any free iodine dissolved in it, but it contains a sediment of oxide of iron. The sediment in a watery solution of iodide of iron, according to Berzelius, is an oxyiodide of iron, probably $\text{Fe}_2\text{I}_3 + \text{Fe}_2\text{O}_3$. The following will explain this: $4\text{FeI} + 3\text{O}$, form in the dark $\text{Fe}_2\text{I}_3 + \text{Fe}_2\text{O}_3 + \text{I}$.

As experiment No. 2 shows, the oxyiodide is decomposed by exposure to the light, the sediment no longer contains any iodine, and the proto-iodide of iron again formed Fe_2I_3 and $\text{Fe}_2\text{O}_3 + 2\text{I}$. But this iodine, which, according to the formula, is free, can no longer be tested by starch, and the principal purpose of this examination was to ascertain what had become of it. The most simple explanation is, that hydriodic acid had been formed. To test for the hydriodic acid, about one pound of the decolorised syrup was put in a glass retort, and heat applied until half-an-ounce was distilled over. This liquid was found to be a watery solution of hydriodic acid. Nitrate of silver produced a yellow precipitate of iodide of silver, and starch became blue upon the addition of chlorine water.

A solution of iodine in sugar and water, in which iodine is more soluble than in water, has a dark red colour; sun-light changes it to white, and no free iodine can be found in the decolorised liquid, and all reactions show that the iodine is changed into hydriodic acid. The same change takes place in an alcoholic solution of iodine, and in a watery solution of iodine in iodide of potassium. The process given above is a very easy and simple one for testing syrup of iodide of iron for hydriodic acid. How far the medicinal properties of the syrup are affected can only be determined by the careful observation of physicians; but it is obvious that a dark syrup should never be used, in consequence of its containing free iodine.

PHYSICAL SCIENCE.

On the Property possessed by Platinum rendered Incandescent by the Battery to produce Gaseous Combination, by M. E. SAINT-EDME.

I WILL first draw attention to the sensibility of iodised starched paper, as a reagent for oxygenised compounds of nitrogen, hyponitric, and nitric acid, infinitely minute traces of which existing in a medium sufficing to blue very decidedly the iodised starched paper.

M. Leroux's experiment, which consists in obtaining ozone by passing a current of air on a platinum wire,

made red hot by electricity, has led me to examine whether oxygen alone could be modified under the same conditions. I find that pure oxygen passing in contact with a spiral, rendered incandescent by an electric current, has no effect on iodised starched paper, and consequently does not seem to be modified. If, on the contrary, oxygen and nitrogen are made simultaneously to impinge on the red spiral, the issuing gas strongly colours iodised starched paper blue, and litmus paper red; hence, I conclude, that under these conditions nitric acid is formed. I am about to continue these researches with various gases.—*Comptes-Rendus.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 20, 1861.

W. DE LA RUE, Esq., in the Chair.

Two Papers by Mr. VERNON HARCOURT were read "*On the Peroxides of the Alkaline Metals*," and "*On the Estimation of Nitric Acid*," and one by Dr. MARCET, "*On the Constituents of Gastric Juice*."

Dr. ROSCOE then delivered the following discourse "*On the Application of the Induction Coil to Steinheil's Apparatus for Spectrum Analysis*":—

It is not possible for me this evening to deliver a formal discourse on the subject of the application of spectrum observations to chemical analysis, because the time which has elapsed since the first discovery of this new mode of detecting the elementary bodies is so short, that we are as yet incompletely acquainted with either the power or the capabilities of the valuable instrument which we propose to employ; but I do not know that I need apologise to the Fellows of the Chemical Society for bringing before their notice any new facts, however incomplete, that may at all serve to illustrate the progress of this new and most interesting branch of our science.

It would be unfitting were I here to enter into details or to give the result of the application of the method of spectrum analysis to the detection of the metals of the alkalies and alkaline earths. All of us must have read the important papers of Bunsen and Kirchhoff with a great deal of interest. What I propose to do this evening is to lay before you the method which the German professors intend to employ for the purpose of applying this method of research, not merely to the metals of the alkalies, or the alkaline earths, but to all the metals—we may hope so—and I think our hope is well-founded, and to the non-metallic bodies as well.

Before, however, I pass to the main subject, there are one or two points connected with the application of this method for the detection of the alkalies and alkaline earths, which, as they are of general importance, it may be well to mention.

In the first place, the property which incandescent bodies possess of giving spectra consisting of bright lines depends upon the substance being in the gaseous form. The spectra of luminous gases are broken; those of luminous solid bodies are continuous. In the gaseous state a heated body between certain given limits emits only a few kinds of light of different degrees of refrangibility; whereas a solid body, when heated, emits, between the same limits, rays of every degree of refrangibility. In order, then, that the peculiar spectrum of any substance may be formed, the incandescent substance must be in a gaseous state. It must be exposed to a temperature at which the tension of its vapour is appreciable. The greater the amount of its incandescent vapour present in the unit of space—that is, the higher the temperature or the more volatile the substance, the

greater does the intensity of the spectrum appear. Kirchhoff and Bunsen showed in the first place in their paper to which I have referred, that all the volatile compounds of a given metal produce the same bright lines; that these bright lines may be taken as certain indications of the presence of the metal, and that from the absence of such bright lines we may conclude the absence of any salt of the metal which is volatile at the temperature of the experiment.

They likewise showed that the range of the temperature within which these bright lines produced by any given metal remained constant is extremely large. The lines are produced by heating a body by the flame of sulphur, of which the temperature is only 1820° ; and that produced by heating by the oxyhydrogen flame, in which the temperature is calculated to be above 8000° ; and that produced, also, when an electric spark is allowed to pass from the poles of the metal in question, the temperature of the electric spark being vastly higher than the oxyhydrogen flame. Through these very different ranges of temperature we find we get exactly the same character of lines, that these lines remain fixed and show exactly the same relative position at a high and at a low temperature; and with perhaps the exception of the combining weights, there is no other single property of the metallic elements which remains so constant and serves so well to distinguish the metallic bodies through so wide a range of temperature as this property of the production of certain bright lines in their spectra;—this power of the vapour of metallic compounds to give off certain rays of a definite refrangibility. On the extraordinary delicacy of this investigation and the unlimited field which is opened out by inquiry, I need not now speak. The apparatus which was figured in Bunsen and Kirchhoff's paper has been superseded since that time by one more convenient, and which is in many respects more useful. I have here several of the apparatus—one made in Germany, one kindly lent by Dr. Faraday, and one made on the model of this by Mr. Ladd. These two instruments are made by Steinholt, of Munich. They possess the advantage of being first rate pieces of optical workmanship, the Munich prisms being of world-wide celebrity; and then they possess the other advantages of being more easily moveable and being more firmly fixed. The heavy iron stand renders the thing more secure. The great advantage, however, of this mode of arrangement is the fact that we can use two spectra from two flames; for the back of the slit carries a small prism, which is placed over the upper half of the slit in such a position that the light from one flame, which we place at the side, can fall upon the small prism and be refracted through the prism in this direction parallel to the axis of this tube; so that in that way we get one image from the flame on the right, which passes through the upper half of the slit, and is seen in the lower half of the field here, because this telescope reverses it; and we get, in the second place, the light from the lamp on the left, also, passing into the telescope and through the lower uncovered half of the slit. This is particularly useful, of course, when we have to detect any given substance. If we are looking for lithium, for instance, and are not sure of its presence, we have but to place a piece of a lithium compound in, and we at once see whether the two lines exactly coincide. If they do not, we know there is no lithium present. If the coincidence is perfect, if the red line passes at once all through, then we are quite sure that lithium is present in the body which is undergoing investigation. These apparatus, however, are very useful, inasmuch as the breadth of the slit can be altered at pleasure, and, owing to the accurate workmanship, we can see the double line "D" of the solar spectrum, and the soda line is easily distinguished as double, and we may also see the lines of which I shall have myself afterwards to speak.

In referring to these diagrams of the spectra of the

alkalies and alkaline earths, I would only remark that these diagrams are given by Kirchhoff and Bunsen, not as accurate representations of what we absolutely see with a good instrument when we pass one of these substances in the flame. Bunsen distinctly states in his paper that these lines were drawn so that only the most distinct lines should be seen. These are not intended to give the absolute representation, but to give such a representation as may be most easily applicable for the purpose of chemical analysis. If we were to represent all the lines which are seen, it would be much more complicated. And Bunsen very wisely thought it would be best to take such a breadth of slip that only the most important lines of the solar spectrum, and in the spectra of the alkaline metals, should be visible. I ought also to mention that Bunsen and Kirchhoff were by no means the first to observe the particular lines of metals. In their paper they begin by saying it is well known that certain bodies when placed in a flame produce spectra containing brightly-coloured bands. They were acquainted with the researches that had gone before. I have their own authority for saying this. In our own country, Talbot, and Wheatstone, and Dr. Miller observed closely the same thing; at all events, they observed some of the points which were noted by Bunsen and Kirchhoff, but to Bunsen and Kirchhoff belongs the honour of having first brought the subject to a definite issue, and made it a distinct and prominent branch of chemical analysis. The most interesting point so far as we yet know regarding the discoveries which have been made by this method, is, of course, the discovery of the two new alkaline metals. The first of these, cesium, was discovered in the springs of Dürkheim and Baden; and he found that most of the springs containing chloride of sodium also contained this cesium. It is very widely distributed in most springs containing chloride of sodium. In forty tons of this Dürkheim water, he obtained only five grammes of cesium. The atomic weight of cesium is 123.4. An extremely high atomic weight, and one which bears no relation to the atomic weights of the other alkaline metals, lithium, sodium, and potassium, which have a common difference of sixteen. The same common difference does not exist in the case of cesium. The chloride is soluble, and deliquesces in the air; the sulphate is anhydrous, and so soluble that one part of water at 20° Centigrade dissolves one and a half of the salt. Water at the same temperature dissolves only about one half its weight of the sodium sulphate. The nitrate crystallizes, and is also anhydrous; the salt crystallizes in the hexagonal system, and is therefore isomorphous. The carbonate of cesium is soluble in alcohol. In this respect it differs from carbonate of potassium. The double platinum salt is most insoluble in water. And this is the mode in which he first separates the two substances. The second new alkaline metal is rubidium, so called from the splendid red lines which it gives. It gives two red lines, splendid beyond anything we can see in the visible continuous spectrum of the luminous gas flame. They are of an extremely low degree of refrangibility. From these two magnificent lines, he gives it the name of rubidium. This gives all the reactions of potash, and forms the platinum salt; therefore it is extremely difficult to separate it from potassium and cesium. From what I heard the other day, we may hope soon to have a full account of Bunsen's researches on those two metals. I believe he has very nearly finished his paper upon the subject.

It is obvious that only the spectra of such can be examined by means of the colourless gas flame as are volatile at the temperature of the flame. If the bead of the calcium salt remains long within the flame, it loses its red tinge, which calcium gives it, and we see no longer the characteristic spectrum of the calcium. This is not because the calcium salt is volatilised, but because it has become basic, and the basic salt is not volatile at the temperature of the flame. You will see also that the

magnesium salts are not included in the diagram of the alkalis and alkaline earths, because the magnesium salts are either non-volatile at the temperature of the flame, or are very easily decomposed. There are, indeed, a few salts of the heavy metals, such as the salts of copper, which tinge the flame, and which, therefore, give the spectrum peculiar to these metals; but by far the greater number of the metallic salts are non-volatile at the temperature of the flame, and require peculiar means of producing the incandescent vapour of them, in order to arrive at the result. By far the best and most generally useful manner of obtaining the characteristic spectra of the metals, is by employing the electric spark, and to observe the spectrum thus produced. Every metal can thus be readily converted into vapour, and bright lines distinctly seen. The easiest mode of obtaining a succession of sparks in less time than the impression on the retina remains, is by employing a spark from a powerful induction coil, such as we have here; by placing the Leyden jar with the outer coating in connection with one of the wires of the induction coil, and the inner coating in connection with the other wire, we obtain a much brighter spark than we otherwise should obtain. Masson has shown that the luminosity of the electric spark is in proportion to the heat, and the heat is dependent on the amount of electricity which passes from time to time; so that the larger the jar, and consequently the greater the amount of electricity which is discharged, the greater will be the amount of heat, and the greater will be the amount of light produced. In this way we can easily obtain a bright spark. [Experimenting.] This we can use, as I shall explain, for the purpose of seeing the spectra produced by the various metals. Wollaston, who first observed the dark lines in the solar spectra, was also the first to observe the bright line in the electric spark. Fraunhofer, in the year 1814, also observed many of these lines. Mr. Faraday appears to have been the first to declare that the electric spark consisted only of ponderable matter, heated in the same manner, and according to the same laws, as the voltaic current heats and volatilizes a metallic wire. Wheatstone, in the year 1835, at one of the meetings of the British Association, was the first, I believe, who pointed out that the spectra produced by the sparks from the poles of different metals were dissimilar; he concluded that the electric spark results from the volatilization or ignition, not of combustion of ponderable matter of the poles. The tables which accompany Wheatstone's paper are very incomplete; and although he first pointed out the practicability of employing such a method for the detection of the metals, his observation seems to have attracted but little attention. "These differences," says Wheatstone, "between the spectra observed when a spark passes, are so obvious, that any one metal may be instantly distinguished from others by the appearance of its spark."—I suppose he means the spectrum of its spark,—“and we have here a means of discriminating more readily than by chemical examination, and which may be therefore employed for useful purposes;”—he means, of course, the electric spark from the machine. Masson was the next, in 1851, to observe the light-giving power of the electric spark, and to observe the spectra thus produced by the spark passing from poles of different metals; and in his paper “On the Luminosity of the Electric Spark,” he devotes a certain portion of space to the consideration of the spectra produced by the passage of the spark from the various metals.

It is to the Swedish philosopher Angstrom, who, in the year 1855, investigated the subject so thoroughly, that we are indebted for the greatest part of our knowledge. Angstrom was the first, previous to Bunsen and Kirchhoff, to draw attention to this important fact, that the spectrum we observe from the spark passing the platinum wires is really due to the super-position of two spectra, and that the one spectrum is produced by the ignition of the simple

particles of platinum, which are mechanically carried over from pole to pole, and heated to an enormously high temperature, and volatilized—that is, that one set of bright lines is owing to the ignition of the platinum, and the other set is owing to the ignition of particles of air through which the spark passes; and that, in fact, when we pass the spark through the air, we have two spectra, one consisting of the metallic spectrum, properly so-called, and the spectrum produced by the gas through which the metal passes. Now, these differences of brightness and distinctness of the lines produced by the air, is quite as great as the brightness and distinctness which the spectra of the metal itself possesses. In fact, we cannot distinguish between the two until we use some other mode of discrimination than I have yet spoken of. The effect of the different gases upon the light may be very well, and very easily and distinctly seen by passing the spark, at the same time, through the air from the platinum poles, and through hydrogen gas from two other platinum poles; we shall see that the colour of the hydrogen spark is totally different from the colour of the spark as it passes through the air. And if any gentleman afterwards will look through this, he will see a most beautiful phenomenon indeed. In the upper half of the field he will see the bright metal lines and the bright air lines; whether these are due to oxygen, nitrogen, or carbonic acid remains yet to be decided. Here is the bright spectrum of the platinum lines and the line of the air, and below is a most extraordinary spectrum, which is the hydrogen spectrum. We will notice the two lines of the platinum which pass through both, for those are extremely faint. First, there is one very splendid red line, which vies in intensity and in beauty with the red lithium line α , which, I dare say, most of you know. And this red line is produced by the hydrogen. Besides this, there is a bright band of green, which can be split up into a vast number of very thin and beautiful green rays. And, further on, there is one bright band of violet, which can also be split up into a great number of separate bands. Between these three bands there is nothing at all. The hydrogen spectrum is a most beautiful and a most peculiar one. The difference of the colour of the sparks is evident to all. The difference of the spectra I can only make visible to those who look through the apparatus.

In this way, then, by using different atmospheres for the same metal, we can tell which lines are due to the air, and which lines are due to the metal itself. We must, of course, in this way make use of the little prism. The light which will come from the hydrogen spark will be refracted through the prism to the upper half of this tube, and the light which comes from the air and the platinum will pass directly through the open slit below into the telescope. Without this arrangement of the little prism on the end of the slit, this experiment would be perfectly impossible. We could not detect which were the platinum lines and which were the lines of the air. I will now pass a spark through, and you will see the red spark of hydrogen, and the blue spark which is shown by the α r. [Experimenting.] There is, however, another way by means of which we may know which are the lines of the metal proper, and which are the lines of the gas; and this of course we can tell by using two sets of poles of different metals. The air sparks pass through both these series of poles, and if we take away this small vessel which contains the hydrogen, and replace it by a similar arrangement to this, which contains, however, instead of platinum poles, poles of iron or copper, we shall then see that certain lines go all through from the top to the bottom; those are the lines of the air, and the lines which are only seen in the upper half of the field are the platinum lines proper; and those lines only seen in the lower half of the field are the copper lines proper, and in this way it is extremely easy to detect the presence of any of those metals. Just as in the case of the

alkalies and the alkaline earths, it is not necessary for the purpose of chemical analysis to have a complete representation of the whole lines, we only need to seek out two or three of the most characteristic and most distinct. Here, in the case of these lines of the metals, we have not to do with one or two lines, as we have to do in the case of sodium,—we have to do with hundreds and thousands, and we only need to look for the most distinct; we only need to distinguish certain lines as always occurring when copper is present, and certain others as always occurring when we have platinum present, and to get these distinctly, and to look for these lines when we want to know whether copper is present. That is the way in which it is done. If we have poles of platinum or poles of iron, we get the same result. If we have, for instance, two sets of platinum poles, we get, of course, the platinum spectrum and the air spectrum. If, then, we want to get the iron spectrum, we only need to moisten the surface of the platinum poles with a little solution of iron—I believe any solution of iron will do,—and we then get at once the bright iron lines. So with any of the metals. In the same way we can obtain spectra of the other metals; and in this way Kirchhoff distinguished, with the greatest ease, between yttrium, erbium, and terbium, lanthanum, didymium, and cerium. Each of these metals possesses distinct and characteristic lines, which are easily recognised and distinguished.

To what extent this method will prove applicable for the purpose of detecting the different salts of the different metals, remains still to be seen. You must remember that I bring these matters before you as mere beginnings of what is, I hope, yet to be done. Of course, very little has yet been done; but still I thought it might be interesting to the Fellows of the Society if I brought before them the method by which these ends may be accomplished. Of the details of the method, of course it is quite impossible for me or any one else to say anything. It would seem, however, that this method, I have just stated, like all other methods that are worth anything, has its difficulties. We often find, on placing two solutions of two metals on the poles, or when we take poles of certain compound metals, that we see only the spectrum characteristic of one. For instance, if we take German silver we sometimes get only the spectrum of one of the constituents of the alloy. This, however, is a difficulty of detail which can easily be overcome. It is not, however, quite so simple as electrolytic decomposition. As in the case of decomposition by the current in the wet way, we find that one metal is deposited before another. This subject is, however, being worked out by our German friends, and we may hope to hear, before long, something more about it.

We will now pass on from this consideration of the power of incandescent gases to give off light of a certain definite degree of refrangibility, or to furnish spectra consisting of certain fixed lines, to the remarkable consequence which Kirchhoff has deduced—that these luminous gases must also absorb light of the same degree of refrangibility as that which they emit. This proposition is the application to the vibrations which we call light of the celebrated statement that a body absorbs all those series of oscillations which it can propagate. Thus, if we sound a certain note in the neighbourhood of a piano, we know that only the corresponding note in the piano vibrates. This proposition Kirchhoff has applied to light; and he not only showed theoretically that this was true, but he confirmed his conclusions by experiment, and he showed that heated sodium vapour which has the power of giving off light only at the one refrangibility D, has also the power of absorbing that ray alone; and that the vapours of other metals, such as lithium, potassium, calcium, strontium, and so on, which have the power of giving off a particular kind of rays, has also the power of absorbing those same rays. If we place sodium vapour

before the slit of our apparatus, whilst the sodium flame is burning, we shall have the sodium light entirely cut off. If while the potassium flame is burning here we put potassium vapour before it, we get these two bright rays cut off. This can be very well seen by a little experiment which was first proposed by Mr. Crookes. He takes a hydrogen flame coloured by sodium, and holds before it a smaller flame coloured still more intensely with sodium. If you look at the hydrogen jet which contains the larger amount of ignited sodium vapour, or sodium vapour of a higher temperature, and, therefore, giving off more intensely the line D—if, I say, you look at that on the background of a light less intense, you see that the sodium flame is surrounded by a dark mantle which is caused by the absorption of the light which passes from the hydrogen flame through the light behind. Another way is to take a tube and put some metallic sodium in it, and then pass in an atmosphere of hydrogen, and after rendering it vacuum to seal it up; and then by gently warming it over a large flame, a tolerably large quantity of the sodium can be brought into a vaporous state at a temperature lower than that at which it attacks the gas. When this sodium tube is held before a piece of white paper and looked at by the yellow day-light we see that the tube appears perfectly black wherever there is any sodium vapour at all. That is to say, the sodium-light cannot pass through; it is absorbed by the sodium vapour, whereas, by the common gas-light it is perfectly transparent.

Kirchhoff found in the solar spectrum lines which coincided exactly when allowed to fall simultaneously into his telescope. That is to say, when the solar light fell through the bottom half, or the uncovered part of the slit, and when the light from a metallic spectrum—the spectrum of iron, for instance,—was allowed to fall into the upper part of the slit, he found that certain lines in the sun corresponded with every line which the iron gave—that there was no iron line which had not its corresponding and coincident line in the spectrum of the sun. The bright iron line and the bright solar line corresponded perfectly. This was found to be the case not only with iron, but with chromium, and nickel, and magnesium. I have here a representation of a drawing by Kirchhoff of a very small portion of the solar spectrum—and it is allowed to be a very beautiful one indeed. It is a chromo-lithograph, but made with tinted inks instead of coloured inks to show the different darkness and the different tints and shadings of the lines on the solar spectrum. This shows the different lines of chromium and magnesium from “E” to “b.” This is “E” [pointing] in the solar spectrum; this is “b” [pointing] so that the whole of these lines occur in the solar spectrum as represented here. Here you see a great number of lines; of which some are iron, some chromium, and some magnesium, and these show the coincidence of the iron lines. This line is a very dark one, and is one of the most easily visible lines in the solar group. It is represented in the map, and marked as little “b.” This is found to be magnesium, and there is also another magnesium line as well. This then is the representation of a very small portion of the solar spectrum as yet given by Kirchhoff. This is only a very small piece of the map which he is about to publish.

In justice to Angstrom we must acknowledge that he came very close upon the explanation given by Kirchhoff. “The analogy,” says Angstrom, “between the two spectra, the metal and the solar, may be more or less complete, when we consider the details. When taken altogether, they produce the impression of one being the reverse of the other. I am, therefore, convinced that the cause of the lines of the solar spectrum involves that of the bright electric lines.” He supposed that it was, and Kirchhoff thought it was. I think the difference between these two will be understood by all. Kirchhoff proved it, and Angstrom suggested that it might be so.

Amongst one or two of the large number of interesting

fields which this has opened out may be mentioned the fact of the experiments and observations which have been made by Sir David Brewster and Dr. Gladstone regarding the appearance of certain other lines in the solar spectrum, lines which are seen under peculiar circumstances, either when the sun is low or when it is high. I am sorry Dr. Gladstone is not in the room. I believe at this moment he is at the Royal Society, giving an account of this same thing. Sir David Brewster found that certain dark lines or bands appeared in the solar spectrum when the sun was low; and these are represented in No. 2 in this diagram—the first red line representing the ordinary solar line; and the lines No. 2 are marked in the second spectrum red, in order to distinguish them from the other dark lines, so as to show that there has been a difference observed. Now, then, Angstrom drew maps of the bright lines which he noticed when the electric spark passed through the air. Now, it is curious that those two sets of experiments, made at different times quite independently of one another, seem to agree in every form. In this way we see very clearly—and I do not know that Dr. Gladstone was aware of this—that Angstrom's bright atmospheric lines correspond very nearly—as nearly as you can expect under such circumstances—with the dark bands observed in the actual observations made by Brewster and Gladstone. Here you see, for instance, between small "b" and "G" there is the same number of bands in both series, and you see the general character of these is the same, so that it appears then that in the atmosphere, even at this ordinary temperature, thick bands or thick columns of gas absorb the same kind of rays which they give off. That seems to be not only true, then, for high temperatures, but it would appear that it is also true of low temperatures as well. That is to say, that at low temperatures certain substances have the power of absorbing the same rays which, at the higher temperatures, they have the power of giving off.

(To be continued.)

NOTICES OF PATENTS.

An Improved Apparatus for Carburing Gas for Gas-lighting. E. C. SHEPARD.

THE specification refers to a particular method of effecting the impregnation of lighting gas with naphtha vapour by the use of an apparatus therein described. A single carburator serves either one or several burners, being placed near or remote as may be most convenient, but preference is given to an arrangement whereby each jet of gas is provided with a naphthalizing apparatus placed near the burner. By means of a float the saturation of the gas by the fluid, hydrocarbon is rendered tolerably constant, notwithstanding the varying depth of this latter in the reservoir, and diaphragms of wire-gauze are employed to ensure uniformity of impregnation.

A suggestion for increasing the illuminating power of coal-gas by the admixture of naphtha vapour was practically and successfully carried out many years since by the late Mr. Charles B. Mansfield, whose enthusiasm in this direction of chemical study led unfortunately to his falling a victim whilst being engaged in the distillation of a large quantity of coal-tar naphtha. Since the period of Mr. Mansfield's original experiments, efforts have from time to time been made with the view of converting the suggestion into a scheme of practical utility. More recently the naphthalizing apparatus has been adapted to the gas-lamps in Moorgate Street, London, and we are assured, as the result of this trial, that, whilst the photogenic value of the light has suffered no diminution, a saving in cost has been effected. The great demand which has lately arisen for the lighter products of coal-tar naphtha to be used in the preparation of the purple dyes

will probably restrict the application to these purposes of the less volatile hydrocarbons, (toluol, &c.), which may nevertheless be well-fitted for employment as auxiliaries in gas lighting.

Treating Lava and other Volcanic Substances in order to fit them for Employment in Certain Arts and Manufactures. R. A. BROOMAN. A Communication. (Not proceeded with.)

THE inventor contemplates the utilization of lava, puzzolano, and other volcanic substances by melting them alone or with the addition of any suitable flux, such as red-lead, borax, lime, potash, or soda; and, accordingly as the heated materials are fluid or pasty, they may be cast or moulded into objects of various shapes; for instance, slabs for tables and mantelpieces, architectural ornaments, tiles, and blocks suitable for building. The specification describes the several mechanical operations to which it is advisable to submit the volcanic matters prior to their treatment in the furnace. Also, it asserts a claim for the employment of the same substances, in the state of powder, for the purposes of a glaze in the manufacture of pottery.

In judging as to the expediency of employing the substances of volcanic origin enumerated in the specification, we are reminded of the oft-repeated attempts to utilize the abundant sources of ready-fused material offered by the blast furnace, and in so many other similar metallurgical operations. Blocks of slag have been used for rough building purposes, and not long since a Company was established (with what success we know not) for the purpose of undertaking the manufacture of useful articles from the unsightly heaps of slag which occupy and disfigure so many acres of land in the neighbourhood of our copper and iron-works.

An Improved Lubricating Grease or Paste for Railway Wheels and all Kinds of Machinery. F. W. SERROTT, Hanover Cottage, Walworth.

THIS invention consists in the use of micaceous ore combined, by preference, with oleaginous or fatty matters, or both together, or other suitable substances, in the manufacture of grease or paste for lubricating the axles of locomotives and carriages, the bearings of engines, and working parts of machinery. The micaceous ore which is employed for this purpose is that well known as a species or variety of hæmatite iron ore found in various parts of this kingdom. It is soft, greasy, and friable in its nature, and forms a good base or principal component part of a lubricant when combined with oleaginous or fatty matters, or both. Being of considerable specific gravity, it has more body or substance than many other materials used for lubricating purposes, and does not so readily run or melt from the action of the sun or continuous working of the machinery to which it is applied, and, therefore, lasts longer, and when properly prepared and mixed with oleaginous or fatty matters will not injure the axles, shafts, axles, or bearings of any engine, carriage, or machine. Most chemists are aware of the apparent greasy properties of some hæmatites. These are here utilised in an ingenious manner; but Mr. Serrott is mistaken if he thinks his idea possesses much novelty. It has been employed frequently for lubricating the bearings of axles and machinery which have to be subjected to great heat.

Brewing Malt Liquors. H. MEDLOCK, Great Marlborough Street, London.

IN this invention the inventor soaks the hops in water, the temperature of which must not be high enough to coagulate the albuminous matter; 160° F. will generally

be found to be the maximum temperature which can be safely used. He prefers a heat from about 120° to 150° . During this process the volatile aromatic substance is produced and dissolves in the water. The albuminous matter is also dissolved, the heat not being sufficient to coagulate it. He then strains the water from the hops, removing by this means the volatile aromatic substance, and albuminous matter. After the hops have been so treated, he boils them with the wort in the usual way, by which he effects the combination of the resinous matter with the gluten of the malt, the absence of the albuminous matter greatly facilitating the extraction of the former, and of the bitter flavour of the hops. The combination of the resinous matter of the hops and the gluten of the malt subsides on cooling the wort, and may be separated from it in the usual way. When the wort has sufficiently cooled, and before or shortly after the fermentation begins, he adds to it the cooled solution of the volatile aromatic substance, which, with the albuminous matter, has been extracted. Mr. Medlock's patent was not proceeded with, —not, we should imagine, from any want of success in carrying it out, for the plan seems to be highly original and ingenious.

Improvements in the Manufacture of Sulphurous Acid, Sulphites, and Bi-Sulphites, and Sulphuric Acid, and in the Application of one of the Products of such Manufacture to the Bleaching of Textile, Animal, and Vegetable Substances. C. A. DREVIT, Rouen. (Not proceeded with.)

To produce sulphurous acid the inventor introduces through an opening into a cast iron retort a quantity of sulphur, which he melts by heat from a furnace; when it is inflamed, the retort is hermetically closed, and a current of air is caused to enter through a pipe through a perforated plate by means of a bellows. The sulphurous acid thus produced passes through a receptacle divided into compartments (in which the flower of sulphur deposits), and is cooled in a leaden worm, whence it is passed into the receptacle with compartments containing either water or a solution of a base or of a carbonate; the free nitrogen and carbonic acid gas (when he employs a carbonate) escape into the atmosphere through an opening.

Paper Pulp. W. CLARK, Chancery Lane, London. A Communication. (Not proceeded with.)

This invention relates to the manufacture of a new pulp for cardboard with tanners' waste, such as spent tan and wazec (sea-weed), which are submitted to various preparatory processes.

Preserving Animal Substances. W. CLARK, Chancery Lane, London. A Communication.

This invention relates to the preservation of animal substances by the employment of talc, laminated or scaly, or of other kinds, and generally in the employment of any other inorganic matters of insoluble nature, or of argillaceous earths, serving as ceramic bodies, or sulphate of baryta, carbonate of lime, and others. All these substances are reduced to powder to be applied on the animal substances, which are preserved in a fresh state, and ultimately brought to a proper state of desiccation. We are at a loss to conceive what possible effect smearing an animal substance over with an earthy powder could have upon its preservation from decay. If the animal matter can be kept perfectly dry it will not alter. If, however, it gets damp, the superficial coating of a perfectly indifferent body cannot save it.

CORRESPONDENCE.

White Gunpowder.

To the Editor of the CHEMICAL NEWS.

SIR,—I find some difficulty in reconciling the account given by Dr. Pohl, and that given by Mr. Hudson relative to the manufacture of white gunpowder. Dr. Pohl speaks of the ease and safety with which it may be manufactured; also of the impossibility of causing it to explode by rubbing between wood and metal, or between stones. And yet Mr. Hudson's assistant almost lost his eyesight by simply crushing some of the larger pieces with a spatula in a porcelain dish. If white gunpowder is to be prepared moist, what is to prevent it caking when dry? and, when caked, is it all to be broken up by hand because it will not bear friction? And suppose the white gunpowder made, dried, and pulverised, what is to prevent it caking again? I apprehend the difficulties and dangers in the manufacture of this material will be found greater than those who are practically unacquainted with the manufacture of gunpowder, black or white, imagine.

I am, &c.

Antidote to the Phosphorus Disease.

To the Editor of the CHEMICAL NEWS.

SIR,—In reading the interesting account in the CHEMICAL NEWS of Aug. 17, of "The Origin and Progress of the Phosphorus and Match Manufactures," by Mr. Gore, my attention was drawn to that part wherein he states that the manufacture of matches "is not without some serious drawbacks;

it produces a most painful disease, which attacks the jaw-bones of the work-people, and causes them to decay." This, of course, is caused by the inhalation of the poisonous garlic odour. Now, it occurs to me, that as arsenic (which also, when heated, emits a strong odour of garlic) has been found useful in malignant or cancerous ulcerations, especially of the skin of the face, in lupus, and Hospital gangrene, and as phosphorus is seen to produce a disease similar to the above, might not the cautious use of arsenic as a prophylactic be tried in this formidable disease? Both give out a garlic odour. The one cures a disease, the other, carefully administered, has been found to cure diseases something akin to the one produced by phosphorus. I am not a believer in Homœopathy, but there is something here, to my mind, like *similia similibus curantur*.

I read of a case lately, where a lady, for long a martyr to asthma, was induced to smoke a small quantity of arsenic with stramonium, beginning with about half-a-grain. After persisting in its use for some time to her great relief, she experienced a complete immunity from the paroxysms of asthma, and much improvement of health. The only inconvenience she felt was, at first, some giddiness and tightness of the eyeballs, which gradually went off. The foregoing preamble brings me to this, viz.:—Might not those operatives who are exposed to the vapours arising from the match composition, and even those affected with disease already, smoke arsenical cigarettes, made of a safe and proper strength?—

I am, &c. HENRY DUNBAR, M.D.
Glasgow.

Preparation of Iodine.

To the Editor of the CHEMICAL NEWS.

SIR,—In the preparation of iodine, after the mother-liquor has been exhausted by the sulphuric acid and manganese, on testing with starch there still remains a considerable apparent quantity. Is there any means of separating it from the residue?—I am, &c.

Chemical Notices from Foreign Sources.

I. GENERAL CHEMISTRY.

Reciprocal Relations of Atomic Weights.

Stas has just published (*Recherches sur les Rapports Réciproques des Poids Atomiques*, Bruxelles, 1860) the results of ten years' experiments, made with the view of testing the truth of Prout's theory—that the atomic weights of all simple bodies are divisible by that of hydrogen. These experiments, we are informed, have been conducted with a care and perseverance never surpassed in the history of experimental investigation, and the conclusion which Stas has arrived at is, that there is no common divisor for the equivalent weights of the simple bodies, and he expresses his conviction that Prout's law, and the later modification of Dumas, are untenable. The differences in the numbers Stas has obtained are not very great, but some of his conclusions are important. We shall return to the work soon for further details, and for the present only quote two or three of the corrected numbers:—

Potassium, 39.13 Silver, 107.943 Nitrogen, 14.041
Sodium, 23.05 Chlorine, 35.46 Sulphur, 16.0371

Hubasse.—A beautiful red-coloured stone has lately been popular in Paris, and brought high prices to the jewellers. Schaffgotsch (*Polytech. Notizblatt.*, Bd. xviii. s. 10) examined a specimen, and found that, when placed in ammonia, it soon lost its beautiful colour, and became a simple piece of rock crystal. It was, indeed, a specimen of quartz, the minute fissures in which had apparently been filled with a solution of carmine.

Preparation of Hydrate of Baryta.—Müller recommends (*Journ. für Prakt. Chem.*, Bd. lxxxii. s. 52) the preparation of hydrate of baryta from sulphide of barium and oxide of zinc. The last is slightly soluble in baryta water, but it can be easily removed by a little sulphide of barium reserved for the purpose. Any traces of sulphur remaining may be got rid of by adding a little sulphate of copper. If any thionic acid is formed during the operation, it may be got rid of by calcining the baryta obtained with a little nitrate of baryta.

II. ORGANIC CHEMISTRY.

Oil of Cajeput.—Schmidt publishes (*Trans. Royal Soc. Edin.*, vol. xxii., p. 360) some researches on cajeput oil. His analysis agrees with that of Blanchet and Sell— $C_{20}H_{16} + 2HO$,—but instead of the name *Dadylo* given to it by these chemists, Schmidt proposes to call the oil the *Bihydrate of Cajeputene*. It boils at $175^{\circ}C$, becomes acid in the air, especially in the presence of alkalis; hydrochloric acid separates a resinous body. When heated to boiling and some sulphuric acid is added gradually, the oil becomes coloured, and between 170° and 175° a liquid distils having the composition $C_{20}H_{16} + HO$, which the author considers the *monohydrate of cajeputene*. The vapour density of this body is 5.02, and corresponds to 4 volumes, which, as it contains an odd atom of oxygen, is an exceptional case. Repeatedly distilled with anhydrous phosphoric acid this monohydrate forms a series of hydrocarbons of different degrees of volatility. The first *cajeputene* $C_{20}H_{16}$ boils between 160° and 165° , and is a colourless liquid, smelling like the hyacinth: it is insoluble in alcohol, but soluble in ether and oil of turpentine. Its sp. gr. at 15° is .850; vapour-density 4.717. Between 176° and 178° , *Isocajeputene* passes; like the former it is insoluble in alcohol, but soluble in all proportions in ether and oil of turpentine.

Paracajeputene comes over about 316° : it is a viscid fluid of a lemon-yellow colour, slightly fluorescent: unlike the two former, it is insoluble in turpentine; in the air it soon changes to a red resin.

Iodine acts on these hydrocarbons when heated, and hydrogen is evolved. Bromine thickens cajeputene and isocajeputene, which are converted into a friable resin by a mixture of sulphuric and nitric acids. Hydrochloric acid colours all three violet, but does not form a definite compound with them. When, however, oil of cajeput is shaken with hydrochloric acid an unstable compound $C_{20}H_{16} + 2 HCl$ is formed, which heated to 160° parts with one equivalent of the acid.

Bichloride of Cajeputene is formed when a current of chlorine is passed through a solution of cajeputene in nitric acid. It is a heavy crystallizable oil with an agreeable smell; it decomposes on distillation, and detonates with nitrate of silver.

The author has also obtained a bromide, $C_{20}H_{16} + 4Br$, and a hydriodate, $C_{20}H_{16} + HI$.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On a New Sulphide of Chromium, by T. L. PHIPSON, Phil. Nat. Doct., Brussels University, Member of the Chemical Society of Paris, &c.

In endeavouring to form sulphochromic acid, Cr_2S_3 , corresponding to chromic acid, CrO_3 , I discovered the existence of a new sulphide of chromium, Cr_2S_7 , which was obtained in the following manner:—

Bichromate of potash is neutralised, and then supersaturated with ammonia; it is then placed in a three-bulb tube and a rapid current of sulphuretted hydrogen is passed through it for a long time. The liquid, sooner or later, becomes dark and cloudy, and then a brown precipitate is formed. This precipitate is Cr_2S_7 . When it is collected upon a filter, the liquid which passes through is dichroic; it is reddish-brown, with green reflections, and probably contains an alkaline sulphochromate. However, upon adding diluted hydrochloric acid to this liquid, care being taken not to saturate completely, I could not obtain Cr_2S_3 (sulphochromic acid), but a new quantity of persulphide, Cr_2S_7 . Here are the analyses:—

I.	II.		
Body deposited during the passage of HS .	Body precipitated by the acid.	Mean.	Calculation for Cr_2S_7 .
Chromium 32.64	32.21	32.42	32.42
Sulphur . 67.36	67.79	67.58	67.58
100.00	100.00	100.00	100.00

This new body is not a mixture of sulphochromic acid and sulphur, $2\text{Cr}_2\text{S}_3 + \text{S}$, but a distinct and definite compound, Cr_2S_7 ; for sulphide of carbon cannot extract any sulphur from it. Besides, the following reactions tend, as well as its composition, to point out its true nature:—

Acids decompose it, with evolution of sulphuretted hydrogen and formation of a chromic salt, whilst sulphur is liberated,—

With caustic soda, chromic oxide, bisulphide of sodium (which gives to the liquid a yellow colour), and sulphur, are formed,—

Persulphide of chromium is easily decomposed, and requires, therefore, to be isolated and dried promptly. In contact with water or damp air it, sooner or later, forms chromic oxide, Cr_2O_3 , and sulphur. When heated it gives off sulphurous acid, and leaves a residue of peroxide of chromium, CrO_2 , of a brown colour, which, when heated more, evolves oxygen, and becomes Cr_2O_3 (green), with evolution of light. When washed and

dried it forms an amorphous powder, of a greenish-brown colour. Its composition renders very probable that of perchromic acid, Cr_2O_7 , discovered by M. Barreswil.

In the dichroic liquid mentioned above, I fancy sulphochromic acid, Cr_2S_3 , must be present, though I have not yet isolated this compound; for as soon as a dilute acid is added to the liquid, the sulphochromic acid set at liberty immediately combines with more sulphur to form Cr_2S_7 , which is precipitated.

When, instead of passing HS into a chromic solution supersaturated with ammonia, this gas is passed into bichromate of potash supersaturated with soda, a very small quantity of brown precipitate is formed, and soon disappears, giving place to a magnificent green precipitate, which upon analysis gave:—

	Found.	Calculated for $\text{Cr}_2\text{O}_3 + 8\text{H}_2\text{O}$.
Chromic oxide. . .	51.61	51.81
Water	48.39	48.19
	100.00	100.00

It is, therefore, the common green hydrate of chromic oxide.

The persulphide of chromium, Cr_2S_7 , is not a sulphide; it does not dissolve in alkaline sulphides, and by this circumstance coincides with certain theoretical data which I shall make known at some future period.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.

(Continued from page 101.)

When equal quantities of sulphate of potassa and chloride of magnesium are dissolved in water and left to crystallise, there is first obtained $\text{SO}_3\text{K}_2\text{O}$, afterwards a double salt $\text{K}_2\text{O} + \text{SO}_3\text{MgO}$, next MgCl , and finally SO_3MgO . (*Berthollet, Stat. Chimie*, i. p. 100.) A similarly varying separation of potassa and magnesia salts may be observed on evaporation of the brine of sea-water. A great many instances are known relating to the solubility of salts, which otherwise are insoluble, in case other salts are present at the same time in the same liquid. Two solutions, the one containing 1 per cent. of carbonate of soda, the other containing 1 per cent. of sulphate of magnesia, do not form a precipitate when added to each other, but a precipitate is immediately formed in case the liquids contain in solution $1\frac{1}{2}$ or 2 per cent. of the said salts.

The magnesia alba which is formed in this case remains soluble in 200 parts of water, while it requires

otherwise 2500 parts of water to become dissolved (*Pyfe*).

If two solutions, each of which contain upon 100 parts of water the first $7\frac{1}{2}$ parts of chloride of calcium, and the other an equal quantity of sulphate of magnesia, are added together, no precipitate will be formed in these 200 parts of water; but the 5.75 parts of gypsum which are here generated, require usually for every 1 part of gypsum 438 parts of water for solution (*Anthon*). (*Brandes in Schweigger's Journ., N. R., Bd. 13, s. 158*).

If a solution of gypsum is added to a solution of a salt of strontia, sulphate of strontia is produced. That precipitate gets slowly dissolved on addition of common salt. This does not take place with sulphate of baryta. Common salt, therefore, dissolves sulphate of strontia.

Gypsum, which requires, according to *Anthon*, 438 parts of water for solution, is completely dissolved in 122 parts of a saturated solution of common salt in water. Rock salt often contains gypsum. Gypsum is also soluble in a solution of acetate of soda, and there is no reason to suppose, that in this case a double salt is formed. If sufficiently strong solutions of sulphate of soda and of acetate of lime in water are added together, and afterwards divided into two equal parts, then it will be seen that on addition of common salt to one of the two parts, that that portion to which common salt was added will become clear, the other remains turbid from the first formed precipitate of sulphate of lime. Lime water, which has become turbid by the action of carbonic acid, becomes, according to *Guyton*, clear on addition of a solution of chloride of potassium or of sulphate of potassa (*Berthollet, Stat. Chim. i., p. 103*).

The solutions of the salts of the peroxide of iron are precipitated by the carbonates of the alkalies, but such does not happen when tartaric acid is, at the same time, present in the solution. Sugar produces the same effect; and although it be supposed for the first case, that the tartrate of iron which gets formed cannot become decomposed by alkalies or their carbonates—which supposition, however, is not in concordance with general chemical rules, even then it is in every case still an anomaly to chemical affinities, that sugar should prevent the precipitation of salts of peroxide of iron. The salts of oxide of copper behave similarly under the same conditions. Oxalic acid behaves in a curious way with salts of peroxide of iron and the so-called yellow prussiate of potassa, ferrocyanide of potassium. In case oxalic acid is present, Prussian blue is also formed, but this, instead of being precipitated, remains in solution (blue ink). There can be no doubt here of real chemical action, since the new compound is equally well formed, but remains in solution.

These, then, are a few instances of what we call physical force exercising influence upon the chemical formation of substances; for there can be no doubt whatever, that these substances do not exist as such in the solutions, when, in accordance with their nature, they ought to have been precipitated long before. The idea we ought to have about these phenomena may be explained shortly, according to *Berthollet*, in the following lines:—

When two salts which are in solution decompose each other mutually, then there are not formed two, but four salts, which do exist in greater or less quantity in the liquid, just as long a time as is required to restore the equilibrium between chemical and physical action. If, for instance, a solution of chloride of calcium and a solution of sulphate of magnesia are mixed together, then there will soon be two other salts in the solution—viz., sulphate of lime and chloride of magnesium. Whether a precipitate

is formed in this case, does not only depend upon the insolubility, or upon the more difficult solubility, of one of the salts in water—in this case, for instance, the gypsum—for we have here not simply water; it entirely depends upon the insolubility of that salt in the saline mixture. In case the substance is insoluble therein, then it becomes entirely thrown down; if it is only slightly soluble therein, then much of it becomes thrown down; if, on the contrary, it is very soluble therein, then none, or only a little, becomes thrown down. A very marked example thereof is exhibited by sulphate of potassa and chloride of calcium; the precipitate, (of sulphate of lime,) which they produce is by far smaller than is in relation to the solubility of gypsum in water. That which remains in solution of the four salts—viz., sulphate of potassa, chloride of calcium, sulphate of lime, and chloride of potassium, is in the state of physico-chemical equilibrium.

Wherever, therefore, we have to do with salts, or generally with substances of different nature which are dissolved together in a liquid, there we have to do more or less with influences similar to those which we have mentioned in the foregoing instances. The experiment of determining silver in the moist way is only excluded from such influences for him, who thinks chloride of silver to be perfectly insoluble, and who despises the great facts brought to light by the master hand of *Berthollet*. He, however, who is deeply penetrated by the truth that probably the presence of some substance, but certainly that of many substances, may exercise its influence on the chemical separation of another substance, will surely investigate with great care if such an influence does exist, and what may be its value in every peculiar case.

As soon as we have to do with pure silver in estimating that metal by the moist way, the presence of these substances which are unavoidably necessary, and which do not seem to exercise any chemical action at all, can, however, be of some notice; but in case we have to do with impure silver, then the influence of these other foreign substances can become so great, as to interfere largely with the results.

The first part of this memoir treats on the investigation of the influence of these foreign substances.

2. **Chloride of Silver.**—The formation of the chloride of silver forms the chief and principal point in the assay of silver by the moist way; and although it may not be our intention to treat here of the generally well-known properties of this substance, still there are some of its properties which must be mentioned if we wish to become thoroughly acquainted with the whole method of assaying silver by the moist way, and of that which has any influence thereupon.

Hydrochloric acid and soluble chlorides precipitate from a soluble salt of silver, white chloride of silver in the form of a so-called curdy precipitate. It is a loosely coherent, flocculent precipitate, which by shaking, or by being heated, collects together the smallest particles of the precipitate and renders the liquid quite clear.

There are only a few substances which yield so spongy a precipitate as chloride of silver. It appears as flocks, the particles of which retain, even after strong agitation of the liquid in which they float about, their coherence, and they even resume that coherence if it has been disturbed momentarily by a strong stirring of the liquid. The smaller particles of the precipitate which float about in the liquid, are taken up in that spongy mass more or less in the same way as the flocks of coagulated albumen render clear a turbid liquid. Application of heat produces movement in the liquid, and what-

ever produces motion in the liquid brings the smaller particles in contact with the more flocculent ones, whereby, while the liquid is rendered clear, the smaller particles are taken up by the larger.

The liquid, after shaking, does not always become perfectly clear; the operator has the faculty, and it is even optional with him, to render the liquid more or less clear. A more coarsely flocculent precipitate is obtained, when after the first addition of the solution of common salt to the silver salt, some of the latter is still left unprecipitated, if then a fresh portion of the solution of common salt is added, and the liquid briskly shaken, the first formed more coarse precipitate takes up very readily the large number of smaller particles of chloride of silver obtained after the second addition of the solution of common salt, and the liquid is rendered always perfectly clear. I shall have occasion to return to this fact, which is of very great importance for the estimation of silver in the moist way.

Chloride of silver is soon discoloured by the light of the sun, being rendered violet and heavy, whilst some chlorine is set free. According to Pohl (*Jahresb. von Liebig und Kopp*, 1851, s. 369) chloride of silver, which is precipitated at a temperature of from 60° to 80° C., is not discoloured by light for many days, if it remains in the liquid kept at that temperature. According to the same, discoloured chloride of silver would become, under these circumstances, somewhat more white, although not quite so white as when it was first formed. These observations, however, I have not found confirmed.

Wittstein (*Report. für die Pharm.* Bd. xxxvi. p. 170) assumes the existence of a subchloride, Cl Ag_2 , in the chloride of silver which is discoloured by light: he affirms that it is not attacked by nitric acid, and that it is decomposed by ammonia into chloride of silver, which is dissolved therein, and into metallic silver, which remains undissolved.

Dumas (*Ch. App. aux Arts*, tome iii. p. 653) is perfectly right when he says, that the quantity of subchloride which gets formed is very small, and the quantity of chlorine which is set free, therefore, very small also. According to Rose (*Analyt. Ch.* ii. s. 400), it is impossible to find any difference in the weight of the white and discoloured chloride of silver, when even a very sensible balance is used. A quantity of 1 gramme of pure silver was dissolved in nitric acid, and precipitated by a solution of common salt added in precisely sufficient quantity to obtain the point of chemical neutrality,—there was, therefore, neither excess of silver, nor excess of salt,—the bottle containing the precipitate was exposed to light, and sufficiently shaken from time to time, in order to discolour as much as possible all the particles of the chloride of silver. I did not find in the liquid afterwards a larger quantity of free chlorine than could be saturated by 6.25 milligrammes of silver. One gramme of silver forms 1.33 grammes of chloride of silver. The 6.25 milligrammes of silver required to saturate the chlorine which was set free in this experiment, represent only 2.06 milligrammes of chlorine; in case subchloride of silver only had been formed, the half of 0.33 gramme, that is 0.165 gramme of chlorine, should have been set free. In this experiment only $\frac{1}{8}$ chlorine of the chloride of silver had been set free. It is accordingly perfectly possible to weigh the difference, and therefore what Rose mentions is not quite correct.

The violet-coloured matter which is formed when chloride of silver is exposed to light is a mixture; part of it is perfectly soluble in liquid ammonia, while

another part of it gets decomposed by ammonia, of which part again is rendered insoluble, the latter being metallic powder.

Some chloride of silver, which had been precipitated from a solution of nitrate of silver by means of common salt, and which had been exposed for some time to the light of the day, was carefully freed from the supernatant liquid, and some liquid ammonia was poured over it. Nearly all of it got dissolved, a small portion of it only, after having been in contact with excess of strong liquid ammonia for some time, remained insoluble. This small portion exhibited the same colour as the powder of minutely-divided silver, as it is separated, for instance, by precipitation by formic acid; it did not possess any violet tinge, and therefore the violet tinge of discoloured chloride of silver cannot be attributed to this substance.

The metallic particles, which are insoluble in liquid ammonia, are of variable size, few of them are so large that they can be retained by a filter. They are soluble in nitric acid, and the solution is precipitated by a solution of common salt; these small particles are, therefore, metallic silver.

Besides these particles of metallic silver, violet coloured, flocculent chloride of silver, when dissolved in liquid ammonia, gives rise to the formation of a colourless liquid, which being supersaturated with nitric acid, yields again pure white chloride of silver, all the violet colour being gone. The explanation of these phenomena is the following:—Daylight in fact reduces a small portion of chloride of silver to subchloride; from Cl Ag is made a small portion of Cl Ag_2 , which latter has a violet colour. If to the Cl Ag_2 ammonia is added, or if ammonia is poured over it, it then yields a colourless solution, while metallic silver is separated, and from Cl Ag_2 there is made Cl Ag and Ag . The former is readily dissolved in ammonia, and can be reprecipitated again as white Cl Ag on addition of excess of nitric acid. The silver can be dissolved by nitric acid. Wittstein's observation, therefore, is quite correct. Even on being warmed with it, nitric acid does not change violet-coloured chloride of silver to white; chlorine water, however, produces this effect instantaneously. The reason why chloride of silver, which is so readily changed by the daylight into subchloride, is not totally changed into it, is entirely due to the chlorine which is set free. An excess of chlorine is an impediment to the formation of the violet material, a little chlorine prohibits its formation. This also is an interesting instance of the influence of mass on chemical affinity.

(To be continued.)

PHARMACY, TOXICOLOGY, &c.

On Coca, or Folha Sagrada—Erythroxyton Coca.

T. PECKOLT reports, in *Archiv. der Pharmacie*, ciii. pp. 39—42, on the following paper of Dr. Valdez:—

Coca is the leaf of a shrub, growing to the height of not over six feet, and cultivated almost exclusively in Peru and Bolivia, recently also in the Brazilian province of Alto Amazonas. At the time of discovery the plant was used only by the Incas and the royal family, and looked upon as the image of a deity. Nobody entered the enclosure or sanctuary where it was cultivated, without previously kneeling down as a sign of adoration. Sacrifices were believed not to be acceptable unless crowned with a twig of this shrub. Oracles would not

answer, and their prophecies were terrible, if coca was not chewed on interrogating them. The Indian found consolation with this divine plant in all misfortunes and when praying for happiness.

Gradually its use extended to the whole population, and it became an important commercial article. Shortly before the independence from Spain, Peru produced coca valued at 2,841,487 dollars, and the leaves circulated occasionally as money. The Indians, in using them, are thereby enabled to perform the hardest mining operations in the midst of deadly metallic exhalations, without resting, and without protection against the unfavourable influences of climate. They march hundreds of miles through deserts, and over steep mountains, subsisting solely on coca, and frequently carrying burdens over places impassable for beasts of burden. Some travellers ascribe this astonishing frugality and abstinence from food to the effect of habit, without remembering that the Indians are naturally very voracious, and lose their strength when abstaining from chewing the leaves.

Coca leaves have a faint and agreeably aromatic odour, particularly when chewed; their taste is somewhat bitter and astringent, and colours the saliva green. They are strengthening, giving tone to the stomach, and are employed against intermittents, though with less decided results than cinchona. They are mixed with lime prepared from certain plants, and used like betel in the Indies. With it and a handful of roasted corn (maize), an Indian travels a hundred miles afoot, keeping pace with a travelling horse. Travels in the Andes are undertaken with an Indian, and it happens on hot days, that the horse is fatigued before the Indian.¹

It is a narrow leaf, little over an inch in length; there are two species, one 2, the other $1\frac{1}{4}$ inches in diameter (length?). The former is called *cacha*, and is superior and more esteemed than the commoner one, which is used only in cases of need and by the poorest people. The culture of this shrub is very troublesome, it being subject to the attacks of a little insect, which sometimes devastates a whole plantation in a single night. Three years after planting, the shrub commences to bear fruit. The harvest of coca, called *palla*, is very laborious, and usually left to women; they commence at dawn to collect the coca into little trunks, leaf by leaf, with the greatest care, so as not to break the stalks or otherwise injure them; a good workman fills ten such little trunks by night. The collected leaves are dried in the sun for two or three days with great care, so as not to become wet or moist, whereby they would be entirely ruined. This procedure is called *seca*, the box containing the fresh leaves *gerga*, and the collectors *palladoras*. The leaves are afterwards packed in bags of 1 arroba (= 32 lb.), and sent to the cities, among which Cusco receives the largest cargoes; from here all the departments of Peru and Bolivia are supplied. But a few years ago, coca was cultivated scarcely outside of Valles de St. Anna; now there are plantations at Paz, Cochabamba, and Alto-Peru, but the quality is inferior.

Coca drank as tea has the same aroma and taste as the finest pearl tea, without any stimulating qualities; from its numerous good properties, it promises to become an important commercial article of Peru and Bolivia.

¹ It has been variously proposed to supply emigrant and other ships with coca leaves, to be used as food in case of shipwreck and other accidents. Their introduction into the army and navy has likewise been advocated, and it is likely that they will be employed in some of the European armies, in order to test their efficacy in keeping up the strength and vigour of the men in urgent cases when food cannot be had.

PHYSICAL SCIENCE.

On Nöbert's Test Plate and the Striae of Diatoms,
by W. S. SULLIVANT and T. G. WORMLEY.

THE limit of the resolvability of lines, or how small a space can exist between lines and still admit of their being separated under the microscope, appears to be an undecided point. Professor Queckett ("Treatise on the Microscope," third edition, p. 238, 1855) asserts that "no achromatic has yet been made capable of separating lines closer together than the $\frac{1}{75000}$ th of an inch." In the same work, p. 245, it is stated that Mr. Ross found it impossible to ascertain the position of a line nearer than the $\frac{1}{80000}$ th of an inch. We also find on p. 512 that Mr. De La Rue, in his extended examination of Nöbert's test plates, was unable to resolve any lines closer than the $\frac{1}{81000}$ th of an inch. In Professor Carpenter's work ("The Microscope," second edition, p. 189, 1859), this sentence occurs:—"The well-defined lines on Nöbert's test plates have not yet been resolved when they have approximated more closely than the $\frac{1}{85000}$ th of an inch."

From the foregoing, it appears that actual experiment fixes the limit of resolvability at about $\frac{1}{75000}$ th of an inch. This does not, as is said, vary widely from the deductions of Fraunhofer and others, based on the physical properties of light. In this connection the remark (*op. cit.*, p. 47) of Professor Carpenter may be cited, "there is good reason to believe that the limit of perfection (in the objective) has now been nearly reached, since everything which seems theoretically possible has been actually accomplished."

On the other hand, there are authorities who assert that lines much closer than the $\frac{1}{85000}$ th of an inch are resolvable. A few years since Messrs. Harrison and Sollitt published (*Microscopical Journal*, vol. ii., p. 61, 1854) their measurements of the striae of several diatoms, assigning to *Amphipleura pellucida* striae as close as the $\frac{1}{150000}$ th to $\frac{1}{180000}$ th of an inch. These measurements have recently been repeated, and with exactly the same results, by Mr. Sollitt alone (*Mic. Jour.*, viii., p. 51, 1859), who furthermore expresses the opinion that striae as close as the $\frac{1}{175000}$ th of an inch, can, with proper means, be seen. Mr. Sollitt's measurements have been adopted in the *Micrographic Dictionary* (1860) and most of the modern works on the Microscope, no one, Professor Carpenter (*op. cit.*, p. 183) excepted, suggesting a doubt as to their accuracy; on the contrary, their correctness seems to be expressly recognised by Dr. G. C. Wallich ("Ann. and Mag. Nat. Hist." for February, 1860).

Such being the conflicting testimony and opinion of distinguished microscopists on the capacity of the modern objective for separating lines, it is somewhat surprising—in view of the high state of perfection now attained by the microscope, and of the number of its zealous devotees—that so few experiments have been made bearing on this interesting point.

As a contribution toward that object, we propose to offer presently an analysis from actual measurements, as far as we were able to carry them, of one of those "marvels of Art," Nöbert's Test Plates. In such investigations the quality of the instruments used being all-important, we would state that the optical apparatus at our command was ample, consisting of a first-class Smith and Beck microscope stand, a Tolles' $\frac{1}{16}$ objective of 160° angular aperture,—an objective of rare excellence in all

respects,—besides $\frac{1}{16}$ ths and $\frac{1}{8}$ ths of other eminent opticians, both English and American; also a solid eye-piece micrometer by Tolles, and an improved cobweb micrometer of Grunow's accurate workmanship. Smith and Beck's stage scales furnished the standards for fixing the micrometrical values of the eye-pieces. By means of Tolles' amplifier, an achromatic concavo-convex lens between the objective and the eye-piece, an amplification (by the standard of 10 inches) as high as 6000 times was obtained. This high amplification, with sunlight variously applied after passing through a small achromatic lens of long focus, was effective in resolution, and essential to the distinct counting under the micrometer, of the lines of the test plate. The test plate used consisted of 30 bands of lines, each band varying but little from the $\frac{1}{100}$ th of an inch in width, and having its lines a uniform distance apart. On one end of the plate is engraved by Nobert, in parts of the Paris line, the distance apart of the lines composing the first band, and thence on, the distance between the lines of every fifth band, as in the second and fifth columns of the following table:—

Band.	Par. line.	Eng. in.	Band.	Par. line.	Eng. in.
1	0'001000	11228	20	0'000167	87118
5	0'000550	20271	25	0'000143	76787
10	0'000275	40542	30	0'000125	80000
15	0'000200	50667			

We add the third and sixth columns, giving the distances in parts of the English inch found by multiplying the decimals in the second and fifth columns by .08835.

Analysis of Nobert's Test Plate of Thirty Bands.

Bands.	Lines in each band.	Parts of an English inch.	Bands.	Lines in each band.	Parts of an English inch.
1	7	11228	16	30	87118
2	8	13082	17	31	88833
3	9	15073	18	32	90548
4	10	17100	19	33	92263
5	12	20271	20	34	93978
6	13	23442	21	36	95693
7	15	26613	22	37	97408
8	17	29784	23	38	99123
9	20	32955	24	40	100838
10	22	36126	25	41	102553
11	24	39297	26	42	104268
12	25	42468	27	43	105983
13	26	45639	28	44	107698
14	28	48810	29		109413
15	29	51981	30		111128

The figures in the third and sixth columns, showing the distance apart of the lines in each band, are the mean of numerous and slightly variant trials, particularly on the higher bands. Up to the twenty-sixth band there was no serious difficulty in resolving and ascertaining the position of the lines, but on this and the subsequent ones, spectral lines,—that is, lines each composed of two or more real lines,—more or less prevailed, showing that the resolving power of the objective was approaching its limit. By a suitable arrangement

¹ The tendency of lines near the limit, either way, of the objective's resolving power, to run into each other and produce spectral or spurious lines, is readily shown by a low objective on the lower bands. Hence, the mere exhibition of lines is not always conclusive evidence of their ultimate resolution. A practised eye will generally distinguish the false from the true. Recourse to a higher objective often accomplishes the same; but when these fail, the micrometer only, together with a previous knowledge of the actual position of the true lines, can determine whether the lines exhibited are real or spurious. A $\frac{1}{16}$ th or $\frac{1}{8}$ th will show the three or four highest bands on this plate regularly and beautifully striped with lines much coarser than the true ones; the same with the $\frac{1}{10}$ th on the test band.

however, of the illumination, these spurious lines were separated into the ultimate ones on the whole of the 26th and very nearly on the whole of the 27th band; but on the 28th, and still more on the 29th, they so prevailed that at no one focal adjustment could more than a portion (a third or a fifth part) of the width of these bands be resolved into the true lines.

The true lines of the 30th band we were unable to see, at least with any degree of certainty; still, from indications, we have no doubt they are ruled as stated by Nobert.

It will be observed that our measurements of the lines on the 1st, 5th, 10th, 15th, 20th bands vary somewhat from Nobert's registration on the plate, as given in the first table above. Such discrepancies are to be expected, and by microscopists familiar with operations of this kind, are looked upon as unavoidable; but that on the 25th band is rather large to be accounted for in this way. We are unable to explain it, and can only say that our repeated measurements of it were very carefully made.

These experiments, together with those of others before noticed, induce us to believe that the limit of the resolvability of lines, in the present state of the objective, is well nigh established; but that this limit may be carried somewhat higher we are not prepared to doubt since the handsome advance lately achieved by Mr. Tolles in his $\frac{1}{10}$ —combining wide aperture, fine definition, and high amplification—shows that the objective had not, as we were inclined to think, reached the stationary point.

The theoretical view of this question,—that is, what may be the closest approximation of lines, consistent with their separation under the microscope—we leave to those competent to the task, by whom, it is to be hoped, we may be favoured with further information on this point.

With regard to the striation of diatoms, an opinion generally prevails that the number of striæ on a given portion of a frustule varies among individuals of the same species, within wide extremes. This opinion is probably traceable in part to one of the earlier publications on the subject, the paper of Messrs. Harrison and Sollitt before referred to, wherein (as in the more recent paper of Mr. Sollitt) measurements of several diatoms are given showing great variableness in their striation. To these gentlemen much credit is due for their discovery of high markings, before unsuspected, on certain diatomaceous frustules; their measurements, however, and the alleged variableness of these markings we have not been able to verify, as will be seen by the following extract from our paper on this subject:—

	Number of striæ in .001"		
	H. and S.	Sm. Syn.	S. and W.
Navicula rhomboides	60 to 111	85	70
Pleurosigma fasciola	50 to 90	64	52 to 56
Pleurosigma strigosum	40 to 80	44	42
Nitzschia sigmoidea	105	85	70

Many frustules of this species, from different localities, have been measured by us, and always with the same results. Pleurosigma fasciola has been specially designated by Mr. Sollitt, and also by Dr. Wallich, as very inconstant in its markings. Of this diatom we are fortunate in being supplied with abundant specimens, from various localities in England, particularly from the neighbourhood of Hull. Several hundred valves, not a few under $\frac{1}{100}$ th of an inch in length, were measured, and on no one were found striæ less than 52 or more

than 56 in '001", much the larger number being 54. A similarly uniform striation has always been observed among the individuals of many other species examined by us.

To such uniformity of striation *Amphipleura pellucida* forms as yet no exception; this diatom is still a "res vexata" among microscopists; neither the striation nor the structure of its frustule is at all satisfactorily understood. The record of its striation is found to be thus:—In 1854 Messrs. Harrison and Sollitt's measurements made its striae 120 to 130 in '001"; Professor Carpenter (1856) first suggests the probability of some error in these measurements; the writers of this paper declared themselves (this Journal, March, 1859) unable to glimpse the striae; Mr. Sollitt (*Microscopical Journal*, Oct., 1859) measures them again and finds them still as low as 120 to 130 in '001", but gives it as the opinion of Mr. Lobb that "even those figures are too low, and that they ought to be set down at 140 in '001"; in the same Number of the *Microscopic Journal*, Mr. Ryland "sees striae, but much more distant than the 130 in '001" of the Hull microscopists;" lastly, Mr. Hendry states (*Microscopic Journal*, July, 1860) that he has "come to a satisfactory conclusion that it is a sad misrepresentation to set down the lines so high in the scale as 130 in '001", and that on a few shells lines may be counted at 42, and many at 60, 70, and 80 in '001". A perplexing record, truly! reminding one of the celebrated Torbane Hill coal case (*Microscopic Journal*, ii., p. 64.)

It is our impression, notwithstanding these conflicting statements, that the diatom before us presented to all these gentlemen the same appearances, but their interpretation of these appearances have been widely different.

The testimony of our objectives, as we understand it, seems to indicate that this diatom has a minutely and irregularly broken-up surface, which, even on the same valve, can be made to show an apparent striation, varying from moderately coarse to extremely fine, according to the obliquity or intensity of the illumination, and to the grade, whether low or high, of the objective used, thus proving beyond question, that the exhibition is illusory. In numerous trials, particularly on fine English specimens from Hull, sent us by Mr. G. Norman, we have entirely failed, with glasses, too, of unsurpassed excellence, to bring out regular, distinct, and unmistakable striae, such as would be at once so recognised by an eye practised on the striae of other diatoms.

After all, it is not improbable that true striae yet unresolved, may exist on the valves of this species, and, furthermore, that the apparent striae of different observers may be similar to the spectral or spurious lines before noted as occurring on the bands of Nobert's Test Plate, when examined by an objective incapable of resolving them.

A summary of the foregoing may be briefly stated thus,—that our experiments lead us to believe:—

1. That lines on Nobert's Test Plate, closer together than about the $\frac{1}{1000}$ th of an inch, cannot be separated by the modern objective.
2. That no true striae have yet been seen on the valves of *Amphipleura pellucida*.
3. That the alleged variableness in the striation of diatoms among individuals of the same species has been greatly exaggerated; on the contrary, we find a remarkable uniformity, thus sustaining the opinion of Professor Smith ("Synop. Br. Diat." v. 2, Introd., p. 26), that for characterising species "striation is the best guide."—*American Journal of Science*.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 20, 1861.

W. DE LA RUE, Esq., in the Chair.

(Continued from page 122.)

After the paper by Dr. Roscoe was read, the following discussion took place:—

The CHAIRMAN: I am sure, gentlemen, you will agree with me that we are always grateful to those philosophers who, from time to time, are willing to bring before us and recapitulate not only their own discoveries but the discoveries of others. The fact is, science is so rapidly advancing, that it is necessary from time to time to halt and to take a retrospective view, and when we do halt, we find ourselves accompanied by a crowd of facts which have broken down the artificial barriers which were formerly raised up to separate one science from another, and it is quite necessary to re-arrange those barriers. It is not an uncommon thing for the physicist to tread upon the ground which a chemist thinks belongs to him, and for the chemist to tread upon the ground of the physicist. Now, we have the chemist occupying the ground of the astronomer, and if the astronomer wants to know something of the constituents of the heavenly bodies, he must come to the chemist. The physicist and the chemist have brought before us a means of analysis so wonderfully exact that, as Dr. Faraday recently said, if we were to go to the sun, and to bring away some portions of it and analyze them in our laboratories, we could not examine them more accurately than we can by this new mode of spectrum analysis. Dr. Roscoe has shown us that Bunsen has been able by its means to discover two new metals which exist only to the extent of five grammes in forty tons of a mineral water—that is, one part in a hundred millions of substance. Only conceive what refinement of analysis and methods of investigation we have now at our command. As we know, Kirchhoff and Bunsen have shown with the greatest probability, that there are certain metals known to us upon the earth existing in the sun's atmosphere. Professor Roscoe has told us this evening that the methods are applicable also to the discovery of the gaseous constituents—not necessarily metals in a gaseous state, but the ordinary gaseous bodies. Professor Faraday has recently given us another proof of the advantages of this method of observation. But I will not occupy your time, gentlemen, by any remarks of my own. There are very many who have given their attention to this subject, and who, I am sure, can throw considerable light on the investigations, and give us very valuable suggestions; besides which, I am aware that Dr. Roscoe is willing to show in a palpable manner the very refined methods which he has recently described, and, therefore, gentlemen, I will first ask you to return your thanks to Dr. Roscoe, and then I will ask any gentleman who may have anything to say on the subject to make his remarks.

Dr. MILLER: By way of starting the discussion, I will first offer a few remarks. No one can have listened to this exceedingly interesting discourse of Dr. Roscoe without feeling the great debt which we owe to those philosophers, Kirchhoff and Bunsen, who have just opened up before us so vast a field. I can only say, that one or two points have struck me since reading their papers which have induced me to make some additional experiments, and I will mention one or two points which have occurred to myself in discussing the subject. I have lately made some experiments with Ruhmkorff's electric coil. I have experimented with one of low power. I used a peculiar arrangement which indicated a difference of power between the two wires which are submitted to experiment. For instance, in the case of platinum the sparks produced are different in length

according to the power which is employed. It is well known from the investigations of Mr. Cassiot, that the negative pole becomes hotter than the other. Bright lines project half way across the luminous field, and those correspond in their starting point with the negative terminal; and on reversing the current, the position of the lines is reversed also, showing that it accompanies the direction in which the current is passing. If then, having put this to the test, you raise the heat by a spirit lamp you get the whole distance traversed by the bright lines, fully corroborating the remark which was made by Dr. Roscoe, that these appearances are solely due to those portions of the metals which are in a vaporous condition. The temperature is not sufficiently raised to establish the whole breadth of the band. There is also another point which struck me incidentally, and which I will mention, if I may be excused for making these desultory remarks. In experimenting with magnesium, Dr. Roscoe remarked that it was not easy to get the magnesium spectrum, obtained from the common salts of the metal. There is a little artifice which may be used, and that is, adding some common salt, by which you facilitate the volatilisation of the magnesium. The definite nature of the light given out by the sodium prevents any confusion in the results, and it enables you to get sufficiently well the lines of the other metal. In experimenting with magnesium wire, if at the same time you let daylight through, certain lines of the magnesium spectrum will be seen to correspond with the lines δ in the solar spectrum.

Dr. FRANKLAND: I am sure, Sir, there can only be one opinion among the Fellows of the Society as regards the beauty and usefulness of this great instrument of analysis which has been placed in our hands by Bunsen and Kirchhoff, and I trust we shall now see our way very clearly to use it. I wish to ask one question of Dr. Roscoe for my own information, and possibly it may contribute to the information of others. I was not here when the Lecture commenced, so possibly the question may have been answered. I have recently read, with very much interest, the beautiful researches which Dr. Miller made some sixteen years ago upon this very subject. It is really wonderful that sixteen years ago we had the real pith of the whole of this matter thrown before us, but up to the present time we have been unable to use it. I will not acquit Dr. Miller from being partly to blame, for, perhaps, he himself ought to have shown us the practical way of employing the instrument at the time it was revealed to us. But in these experiments, I think, if I am not mistaken,—and Dr. Miller will set me right if I am mistaken,—he showed that one and the same element did not yield in all forms of combination the same spectrum. Now, I wish to know how far experiments have been made upon the different metallic compounds, or upon the different salts of the metals, as to whether they really do yield the same spectra as the uncombined metals themselves. Dr. Miller found that nitrogen, for instance, produced certain spectra which were visible in perhaps one or two of its compounds, which were totally invisible in its other compounds with oxygen. Chlorine, again, produced a distinct spectrum, which was visible, I think, in nearly all its compounds with oxygen, but in one or two this spectrum was very materially changed. Now, I think it would be desirable, at the outset of our endeavours to use this process, to investigate this subject, so as to be as well acquainted as possible with the various metals; therefore, I wish to know from Dr. Roscoe how far such experiments have yet been made—how far we can rely upon these spectra as being in all cases true indications of the presence or the absence of what we are seeking for.

Dr. Roscoe: In answer to Dr. Frankland's very important question, I should say, to begin with, as far as regards the alkalis and alkaline earths, there can be no doubt that all those salts which in the colourless flame are volatile, give the same spectra; and if we take the

sulphate, or chloride, or nitrate, we do not see, with the instrument that Bunsen and Kirchhoff propose to use, any difference in the spectra of the different salts of the alkalis and alkaline earths. I imagine the explanation of what Dr. Frankland has just pointed out is to be found in the fact, that those substances, which at the ordinary temperature are gases, or which at a temperature very much lower than the temperature of the flame become gases, require a very much higher temperature to become luminous and give out light, than those substances which are either solid at the ordinary temperature, or very much less volatile. Now, I really cannot speak positively upon this point, nor do I think the subject is so far advanced that we can have positive information on it, but I do not myself suppose if we take the nitrate of strontium and the chloride of strontium, for instance, that in the spectra obtained by the electric spark, we should see exactly the same bands produced by the two compounds. I imagine that we should see in the one case something due to the presence of nitrogen, and in the other case something due to the presence of chlorine. How far this may interfere with the use of the spark, of course, I am not in a position to say. With regard to the beautiful experiments of Dr. Miller, published in the year 1845, I believe that the differences which Dr. Frankland alludes to were due to the absorption of those different vapours. I won't be quite sure whether that is the case. Dr. Miller will be able to give us positive information. I believe that Dr. Miller found that peculiar bands due to the oxides of chlorine were not the bands produced by the luminosity or by the ignition of the chlorine, but dark bands produced by absorption, and in that way, of course, he found different oxides of nitrogen gave different results, some of which gave coloured bands. I do not know whether Dr. Miller observed the luminous spectra of those substances. Thus NO_2 and NO gave bands which the elements themselves did not give.

Dr. MILLER: I may state, Sir, in reply to the interesting statement which has been made by Dr. Frankland, that it seems to me that there is a distinction between those bodies which are metallic and those which are not metallic. In the case of the non-metallic compounds, especially oxides, we have a different series of lines to those furnished by the elements in their uncombined state. For example, notwithstanding the green colour of chlorine, pure chlorine gives no lines to ordinary observation, and hypochlorous acid gives no lines. Chlorous acid and the peroxide of chlorine both give lines, and lines which even appear to coincide. In the case of the peroxide of nitrogen there is a series of lines characteristic of that vapour, which Dr. Gladstone has recently most elaborately investigated. I was not able at that time to isolate nitrous acid, corresponding with the chlorous acid, with such a degree of accuracy as would make the comparison worth anything. As has been stated, there is certainly a difference in the bodies, according to their state of combination. The appearance of lines is not always dependent upon colour. In a great many cases coloured vapours appear to give no lines; in other cases they do give lines. The intensity of the lines does not depend upon the intensity of the colour. A very curious illustration of that appears in the contrast between bromine vapour and the peroxide of nitrogen. Bromine gives a series containing a great number of lines, which look almost as if they were ruled with a ruler from one end of the spectrum to the other, and each of these ruled lines consists of an infinity of finer lines. In the case of iodine a similar appearance is observed, but it is much more graduated. I do not mean to say that they fall with the same intensity; but there is the same regularity and the same kind of gradation from darkness to light. Hydrobromic acid and hydriodic acid both give colourless vapours entirely destitute of lines, except so far as the lines are produced by ordinary solar light.

Dr. FRANKLAND: Would it not follow that if any vapour or gas was incapable of absorbing those rays of a particular refrangibility it would also be incapable of emitting them upon ignition? I think if the theory now propounded would account for those lines, such would be the case. It is only because these particular vapours possess the property of taking up those particular rays which move at a certain velocity that they are capable of absorbing to a great extent the light from the nucleus of the sun, and it is almost proved that when a vapour is incapable of absorbing certain rays of light, it is incapable, also, of emitting those rays at those particular temperatures, at all events.

Dr. MILLER: There is one observation which I should make. In experimenting with the salts of metals I generally use chlorides, because they are more soluble in alcohol. They were dissolved in that liquid, and in this way their flame could easily be examined. I always found that in the case of the chlorides there was a band about the green, and I attributed that to the escape of chlorine. I found in all cases where I used a chloride that I got this band, and I did not get it in other cases where I did not use a chloride. I did not investigate it with a sufficient degree of minuteness to say that it was due to the chlorine or not, but I thought it was due to the escape of the chlorine. I have formerly stated that as my opinion. The effect of the absorptive influence of these compound gases upon light it would be very difficult to ascertain, because none of these compound gases will stand a very high temperature without undergoing decomposition.

The CHAIRMAN: There is one matter, gentlemen, which has struck me in this discussion, and which it is necessary to bear in mind; that is, that with respect to light we do not see all the light, that is to say, all the force emitted by a luminous body, or a body in a state of incandescence, or having a temperature different from that which it has in its normal state. We do not see all the effect, and it is very possible that some of those luminous or incandescent bodies may give off rays which would be visible to a sensitised photographic plate; and that their vapours might also stop off a portion of those rays. Hence, I think it is very desirable that the experiments should be extended in that direction. I do not at all put this forth as an idea of my own, because I am quite ready and desirous to attribute it to the philosopher who propounded it, and that was Professor Faraday. Probably the prosecution of experiments in this direction might lead to the detection of bands which are not visible in the luminous part of the spectrum; I dare say it has struck other philosophers who are pursuing the subject, and it is very likely that investigation will be carried on in that direction.

Mr. HERSCHHEL: There is a question that I should like to ask Dr. Roscoe, if I may be allowed to do so, about the absorption of the sodium ray by the sodium flame. It seems to me that by the explanation given in which it is compared to the action of a sounding-board, that instead of the vibrations being absorbed when they came to it, they ought, on the contrary, to be heightened in intensity, it has always been difficult for me to understand the usual explanation.

Professor FARADAY: It has always seemed to me a very difficult thing to see how of necessity there was a depression of the light instead of an increase and exaltation of it.

Dr. ROSCOE: It seems to me that Mr. Herschel has hit the nail on the head. It is a very difficult point to answer, and I really do not feel myself to be able to give a satisfactory explanation of it. It is quite true that the simile of the sounding-board is not quite an exact one, because the vibration is taken up in the one case, and in the other case it is absorbed. I cannot explain it at all, and I don't know that it ever has been explained. About the fact of the absorption, I have no doubt at all. It appears to me a sort of interference, because certainly the intensity of

the light is diminished, and not increased. The simile of the sounding-board I believe was first given by Mr. Stokes, simply as one which would help us to form an idea how one body, which is capable of taking up a vibration, may be set in vibration by another body at a distance, undergoing the same vibration. It is, however, a matter which I must leave to physicists to explain.

Dr. MILLER: May I, Sir, venture a very crude suggestion upon this matter, as it has been started? May it not arise in this way?—If it is a case of interference, as Mr. Roscoe says, it may arise from the fact that in particular positions of the flame the phases of vibration coincide, and then we have increase; and that in other positions of the flame which is continually flickering, the phases of vibration vary, and neutralise each other. Thus, we may get the black in the one case, and the brightness in the other. I have repeated the experiments, and I have found in some cases an increase of light by interposing the electric light between the sodium light and the eye, and in other cases there has been a dark line produced. Now, may it not possibly arise from the fact of the flickering of this sodium light giving sometimes vibrations which coincide, and therefore reduplicate the light, and at other times the reverse, thus producing darkness?

Dr. GLADSTONE: I think, Sir, I may be permitted to say a word upon this subject, although I did not hear the discourse; for it so happened that it was necessary for me to leave the room to lay before the Royal Society a communication upon the same subject. I had to go and see how they got on there. My paper was read, although there were twenty-one papers before the Society, and there was a vigorous little discussion upon it, so we have been talking in another place upon just the same subject. There are one or two points which have been started in the discussion, which I may just allude to. A thought has been propounded by Dr. Frankland whether a gas which gives no lines of absorption, ought to emit lines when it was heated very strongly. Now, whatever we may think of that theoretically, we know in practice that it is absolutely not so, because nitrogen and oxygen and other gases are in the atmosphere, and in that condition. The second of those maps shows certain lines which make their appearance when the sun sinks towards the horizon—when his rays, therefore, pass through a large stratum of air. Now, it occurred to me that we might find out what constituent gave out these lines, by comparing those dark lines, or lines of absorption, with the brilliant lines given out when various constituents of the atmosphere are strongly heated. Therefore I compared the position of those with the position of the bright lines which appear when nitrogen is strongly heated in tubes by the electric spark, as shown by Angstrom and Plucker. I made the same experiments with oxygen; and I examined also the lines given by the oxy-hydrogen flame, and by carbonic oxide burning in the atmosphere, thinking these two flames might consist, more or less, of incandescent nitrogen and oxygen. The result of this comparison is, that I found no one point of similarity between those lines limited by these gases when strongly heated, and the lines which appear in the atmosphere when the sun's rays go slantingly through it. The conclusion, therefore, is that two or three hundred miles of mixed oxygen or nitrogen gases, do not exhibit any indication that we can appreciate of absorption bands in the same position as oxygen and nitrogen would emit rays, if strongly heated. The same holds good of water and carbonic acid. Hydrogen is the only doubtful gas in the matter; and there may be three of these particular bands which may possibly be due to hydrogen, but I don't think so myself. Another point which I may allude to is this, that we have in this way a most powerful means of showing the absence of certain constituents from the atmosphere. We can all see that if such a substance as peroxide of nitrogen—(and here I must correct a statement of Professor Miller, who described me as having

examined this particular gas: it was not examined by me, but by Sir David Brewster long ago, and all the credit which I can claim is that of putting Brewster's investigations together—but as these lines do not coincide with the dark lines that appear in the spectrum of the sun, we see that there is none of this gas in the atmosphere, or the moisture of the atmosphere would resolve it into other things. But we have the means thus of excluding bromine and iodine from the atmosphere. We have been told by Dr. Miller that these two gases produce most beautiful lines of absorption, which cannot be mistaken when they have been once seen. A small quantity of either will produce these lines. Now, these lines do not appear, and no trace appears in the spectrum of the sun. I calculated the matter roughly, and I found that we should be able to distinguish in this way one part of bromine in 950,000,000 parts of air, and there is not that.

Dr. Roscoe: I can only say one word of thanks to Dr. Gladstone for having mentioned the results of his experiments, which enables me to set myself right before the Society in referring to these spectra. Dr. Gladstone was not in the room when I spoke of them, or else he would have heard that I gave a different account of it, for I only compared Dr. Gladstone's table with Angstrom's table, and saw in it a very fair coincidence, and not having had time to investigate the matter I think it was a very fair assumption to suppose that there really was this absorption by the electric spark; but it appears now that this is not the case, and we must not rely on these drawings, then, but take Dr. Gladstone's own experiments. I only mention this because I stated before that it appears that it was a case of coincidence in the tables published.

Dr. MILLER: I think, in reference to the photography of the invisible lines of the spectrum, it should be stated that experiments have already been made in that direction. Becquerel and myself have made experiments on this, and I recollect some time ago seeing some very nice spectra which Mr. Crookes produced of the lines in the solar as well as metallic spectra.

The CHAIRMAN: It was not with respect to the photography of the spectrum, but with respect to showing photographically the separation or absorption of certain rays which are photographed when the metallic vapours are produced. It only remains for me now to state that the meeting is adjourned to November 7.

NOTICES OF BOOKS.

Lights and Lighthouses: Report of the Commissioners appointed to inquire into the Condition and Management of Lights, Buoys, and Beacons.

SECOND NOTICE.

IN continuation of the remarks on the general subject of this inquiry which appeared on a former occasion in our columns,¹ we have now to pass in review some of the results arrived at, and to point out other promising directions of investigation, which are treated of in detail or suggested by the perusal of the voluminous mass of evidence which has been accumulated by the Commissioners for the purpose of enabling themselves and others to decide upon the best methods of producing and judiciously applying the brilliant lights which serve as beacons on the coasts of the United Kingdom.

The first and perhaps the most important subject of inquiry refers to the character and source of light best adapted to general lighthouse use, and here at once a dis-

inction has very properly been drawn between methods applicable to all localities, and those which are only suitable for illumination on the mainland, or at most to those only which have the advantage of occasional intercourse with commercial districts in the immediate neighbourhood. Thus it is found easy to apply gas for the illumination of the harbour light at Leith Pier Head, but the carrying out of the same system at the Eddystone would, from its isolated position, be attended with much greater difficulty.

In the present state of the subject, it seems to be generally admitted that the use of the oil-lamp is on the whole the most satisfactory, especially in remote situations, but as the result of a canvass of the scientific opinions, it appears that whilst the majority concede this as an established proposition, twelve among the fifty authorities consulted give their votes in favour of other means of illumination. From these we select the following as representing the systems which appear most worthy of comparative trial. The Earl of Rosse recommends the substitution of the lime light, which recommendation is also confirmed by the opinions of Sir John Herschel, Mr. A. H. Renton, C.E., and Mr. William Austin, C.E. We may here remark that by a recent announcement in the *Times* the public is informed that a trial of the lime light was commenced at the South Foreland Lighthouse on Monday, the 26th of August last. Mr. Copeutt recommends that experiments be made with the Fitzmaurice light. Sir David Brewster advocates the use of a gas light fed with pure oxygen. Admiral Fitzroy and Dr. Robinson, of Armagh, suggest the application of oxygen in conjunction with the present oil-lamp. Mr. James Mackintosh recommends a trial of the Bude light. The various modifications of the electric light as proposed by Dr. Watson and Professors Holmes and Way have each their advocates; but on this head we refer with confidence to the reports rendered by Professor Faraday to the Trinity Board. The particulars relating to these inventions form a conspicuous section of the scientific evidence, and to these we propose again to revert. Dr. Robinson suggests that, in the event of the magneto-electric light being found too expensive for general use, the apparatus should nevertheless be provided, and used only during the prevalence of fog or snow. The same gentleman points out the advantage of the naphthalising process employed as a means for increasing the brilliancy of gas, whenever circumstances should render the use of this source of light possible and desirable. Paraffin oil, as a substitute for "refined rape," is preferred by Dr. Joule for use in lighthouses easy of access. Suggestions have also been made in reference to the use of certain pyrotechnic mixtures for producing lights of great intensity; but the objections incident to the employment of this class of materials appear almost insuperable, on account, not merely of the uncertainty in regard to regularity of burning, but mainly by reason of their combustion being invariably attended with the formation of sublimes, which are liable to condense on the inner surfaces of the glass lanterns, and thus materially obscure their transparency.

It is to be regretted that the recommendation to consult Mr. Babbage, who has made many points in reference to lighthouses the subject of particular study, does not appear to have been acted upon by the Commissioners, although the advantage of taking this course was suggested independently by the Earl of Rosse, Sir John Herschel, and Professor C. P. Smyth.

Among the propositions which appear to offer the greatest advantages for illuminating purposes the lime-light, at present under trial at the South Foreland, and the magneto-electric light of Professor Holmes, formerly tried at the same station, have been deemed those most worthy of careful comparative experiment. In order to prepare with facility the gases necessary for the first of these methods, it is recommended to employ the recent

¹ CHEMICAL NEWS, Vol. IV., p. 37.

suggestion of MM. Deville and Debray for procuring oxygen by the decomposition of sulphuric acid by heat; and also to use as occasional substitutes for pure hydrogen ordinary coal-gas and the highly-carburetted gas afforded by the destructive distillation of oil. These when not produced on the spot are to be conveyed thither in strong iron cylinders under powerful compression. It is manifest, therefore, that the employment of lamp-oil possesses in a single particular—that of portability—an advantage over the newer system, especially when applied in difficultly accessible positions.

With reference to the burning of coal as a means of producing light, it is interesting to compare the results obtained by the old fire-basket of the last century with those furnished by the combustion of gas prepared from one portion of coal by the consumption of another; and this system again with that which converts a given weight of coal burnt under a steam-boiler into motive power, and by the employment of this force in the rotation of magnets to produce an equivalent in the shape of the magneto-electric light. The practical solution of this and other equally important problems will not, we trust, be long deferred. These directions of scientific inquiry have a charm not only for Faraday, who introduced them as the subject matter of a lecture at the Royal Institution, but must always be appreciated by those who feel a general interest in these questions in economic science.

As to the optical apparatus, the dioptric system, invented and first employed in France, has been gradually adopted in our own country, and in Scotland some improvements have been made in it. There is, however, this important difference: in France the new apparatus was adopted throughout the whole lighthouse service; and in Spain and the States of America it has lately been exclusively adopted in the great reformation of their lighthouse system just effected by the Governments of those countries; but in the United Kingdom the old reflectors have only been replaced from time to time by the refracting apparatus; and the Board of Trade now lay down the principle that the expense should only be incurred when the reflectors are worn out. A judicious combination of metallic reflectors with the prismatic (dioptric) apparatus of Fresnel will often prove the most efficient arrangement, especially when the light is a fixed one and placed in a position where no illumination is required on the land side.

The distinguishing colours most suitable for lighthouses are red, green, and white; it would appear that white and red have greater fog-penetrating power, but Sir David Brewster justly remarks in reply to this question, that "it is not a matter of opinion, but should be experimentally determined." Sir John Herschel writes, "pale red and pale green give a good contrast, but there is a chance of colour-blind persons not perceiving it." Has the necessity for examining the eyesight of mariners employed on the watch been efficiently appreciated? Dr. George Wilson's researches on the subject of colour-blindness have proved that a very notable proportion of individuals are in some slight degree liable to errors in attempting the discrimination of colour.

Mr. George Gladstone calls attention to the beneficial results likely to arise from the extension of a system of telegraphic communication between lighthouse stations; whereby many disasters at sea might be avoided if it were possible to communicate by a code of signals, the information of coming storm to all vessels within sight.

In concluding our notice, we cannot refrain from offering willing testimony to the value of the labours of Mr. John Hall Gladstone in connection with the scientific questions involved in the inquiry. The suggestions referring to points still requiring investigation have been drawn up by this gentleman in a manner which seems to have exhausted the whole subject.

NOTICES OF PATENTS.

A New Paste made from Wood, to be Used in the Manufacture of Various Articles. C. STEVENS. A Communication.

THIS invention refers to the manufacture of a kind of pulp or paste from the fibrous tissue of wood, the material so prepared being capable of adaptation to many purposes similar to those for which papier maché is at present employed. The treatment to which the wood is subjected may be generally described as follows:—The shavings of soft woods, as poplar, birch, lime, and fir, are used by preference; these are boiled in a solution of caustic soda for a time sufficient to effect the tolerably complete separation of the woody fibres, which are then taken out, drained, and allowed to remain for several days in a mass until fermentation has set in, when the disintegration of the fibres will by this means have been further facilitated. During this operation the mass will require frequent watering to prevent the formation of a hard outer crust upon the glutinous material. Eventually the structure of the fibres will become soft and supple, and may then be further broken up by a kind of tearing engine, constructed of toothed rollers and surfaces, which is fully described in the specification. The washing and after treatment are very similar to the processes ordinarily followed in the making of pulp for paper.

The system of manufacture here defined, yields a description of pulp certainly inferior to that usually employed in paper-making, but which will nevertheless be suitable for moulding into shapes and for a rougher class of purposes where the production from cotton rags would be met by insuperable difficulties on account of cost.

Tanning Hides and Skins. J. H. JOHNSON. A Communication. (Not proceeded with.)

It is proposed to employ for the purpose of tanning hides a new vegetable decoction prepared from maruta cotula, to a gallon of which are added about four ounces of catechu, and two ounces each of alum and common salt. In this mixed tan-liquor the skins or hides, with or without hair upon them, are to be immersed, and there left for a period determined by the thickness of the skins, and by other circumstances which ordinary experience will dictate.

Sir Humphry Davy was, perhaps, the first to show that catechu alone could be employed as a tanning material. We are unacquainted with any special properties possessed by the vegetable decoction referred to, which would render advantageous its employment in conjunction with the foregoing.

Manufacture of Fuel. A. G. LASSEUR, Bordeaux.

THE intention of the patentee is to agglutinate small coal, coke, or anthracite into blocks or lumps of various shapes and dimensions convenient for employment as a compact kind of fuel. In carrying out this process the inventor heats the small coal to a softening temperature in a closed oven, and then, by a suitable mechanical contrivance, effects the complete admixture of the same with either coal tar, pitch, or resin, and moulds the hot plastic material into blocks of the shape required. The treatment of peat, also, in a similar manner is contemplated in the specification.

The general principle upon which the present process is based has repeatedly formed the subject of previous patents for the same object. Many years since the "Patent Fuel" Works were established at Swansea and elsewhere with precisely the aim of converting the dust and small coal into serviceable blocks of fuel, admirably adapted for shipping and other purposes where economy of space

is of the highest importance. By operations almost precisely identical, small coke, also, is daily reconverted into larger masses by the aid either of pitch, tar, resin, asphalt, or similar materials, the number of which is only exceeded by the perfect host of specifications descriptive of these manifold patented processes.

Portland Cement. J. LARK, Streod. (Not proceeded with.)

THIS invention relates to an improved method of drying the mixed materials (marl and chalk) after their incorporation by grinding with water, and prior to being burnt in the kiln to make Portland cement. The moist material is spread out upon the bed of a kind of drying stove, constructed with a series of wrought iron pipes laid underneath, and communicating with a steam boiler, which constitutes the source of heat employed in the process of desiccation. The inventor claims for this system the advantages of greater rapidity in drying, and more uniformity in regard to the degree of heat.

Improvements in Mordanting and in the Manufacture of Products to be Used in Mordants and Otherwise. J. TOWNSEND and J. WALKER, Glasgow.

THE improvements here referred to consist in the substitution of the hyposulphite and sulphite of alumina to be used in preference to other compounds of this base for the purpose of a mordant, particularly adapted to the dyeing of Turkey red. The specification describes the mode of preparing the mordant from alum and other salts of alumina, and likewise refers to the production of "precipitated antichlore" by double decomposition between the sulphite or hyposulphite of lime and a salt of alumina.

Dyes and Colouring Matters. C. H. G. WILLIAMS.

Obtaining Colouring Matters. V. HALL.

Preparing Colouring Matters for Dyeing and Printing. C. A. GIRARD, Paris.

THE patent of M. Girard is that alone which has been proceeded with. It refers to the production of variously-coloured dyes from aniline red by treatment either with aniline or any homologous base.

Mr. Williams' invention relates to the preparation of blue and purple dyes from the organic alkaloids, quinine, cinchonine, strychnine, and brucine; and is partly in continuation of a patent formerly granted to him (April 30, 1859) for the production of dyes from these sources.

The specification of Mr. Hall, of the College of Chemistry, describes minutely the steps taken for the production of colouring matters from the heavy oil of coal-tar, technically known as "dead oil." This is submitted to fractional distillation, and the separate portions severally acted upon with concentrated nitric acid, the nitro-compounds so formed being subsequently reduced by any one of the chemical agents specified, either by sulphide of ammonium, nascent hydrogen, or acetic acid and iron filings.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Action of Ammonia on Chlorides.—M. Deherain has communicated to the Chemical Society of Paris the first part of an extended study of the action of ammonia on metallic chlorides (*Bulletin de la Société, &c.* No. iii., p. 51). When chloride of zinc is dissolved in liquor ammonia, the solution on cooling deposits a white crystalline powder, ZnCl_2NH_3 . The powder dissolved in hydrochloric acid yields, when the solution is evaporated, a well-crystallized salt, $\text{ZnCl}_2\text{NH}_4\text{Cl}$. The ammoniacal liquor which yielded the first salt evaporated at a gentle heat gives another, with half the amount of ammonia, ZnCl_2NH_3 . This salt dissolved in hydrochloric acid, like the former, gives a double salt, $\text{ZnCl}_2\text{NH}_4\text{Cl}$. The salt, ZnCl_2NH_3 , when ignited, loses half its ammonia, and then forms a yellow,

transparent, gummy mass, which is a very stable compound, $2 \text{ZnCl}_2 \cdot \text{NH}_4\text{Cl}$. The author adds nothing to our knowledge of the action of ammonia on bichloride of tin. Protochloride of antimony fused in an atmosphere of ammonia yields on the surface the compound $\text{SbCl}_2 \cdot \text{NH}_3$. Water decomposes this compound, forming a white precipitate, and leaving in solution the salt $\text{SbCl}_4 \cdot \text{NH}_4\text{Cl}$. The compound $\text{SbCl}_2 \cdot \text{NH}_3$ dissolves in hydrochloric acid, and yields on evaporation brown deliquescent crystals of a very unstable salt, $\text{SbCl}_2 \cdot \text{NH}_4\text{Cl}$. When ammoniacal gas is carried into the mass of fused protochloride of antimony, a white volatile salt is formed, having the formula $\text{SbCl}_2 \cdot 2\text{NH}_3$. With perchloride of antimony ammonia forms a compound to which Rose assigned the formula $\text{SbCl}_2 \cdot 2\text{NH}_3$, but which M. Deherain's analyses show contains $\text{SbCl}_3 \cdot \text{NH}_3$; and another, with 4 atoms of ammonia, $\text{SbCl}_4 \cdot \text{NH}_3$. Both of these form crystalline salts when dissolved in hydrochloric acid and evaporated. The author is inclined to regard the compounds of chlorides with ammonia as *chlor amides*, but admits that there are serious objections to the view.

Nitrous and Nitric Acid in the Atmosphere.—Cloeys has proved (*Comptes-Rendus*, T. lii. p. 527) the presence of nitric acid by passing air through solutions of the carbonates of potash and lead. In both cases he obtained nitrates. Other oxygen compounds of nitrogen, the author says, are present in the atmosphere, which makes him doubt the accuracy of the ozonometric observations made with iodized papers.

II. ORGANIC CHEMISTRY.

Formation of Fumic Acid.—The formation of fumic acid, so important, apparently, to the nutrition of plants, has received a long investigation at the hands of M. Paul Thenard, the discoverer of it (*Bulletin de la Société Chimique de Paris*, No. ii. page 33), who has come to the conclusion that it is a compound of ammonia or certain ammoniacal salts with vegetable principles. He wetted straw, dry leaves and sawdust with ammonia, and the carbonate and sulphate, and found that it was formed in abundance. He found, also, that when glucose, or sugar, was heated in a tube nearly to the temperature at which it decomposes, and a current of ammoniacal gas was passed, a large quantity of the ammonia was absorbed, and substances produced greatly resembling fumic acid. That formed from glucose was of a brown colour, was soluble in water, acids and alkaline solutions, but insoluble in alcohol. That formed from cane sugar was brown, uncrystallizable, soluble in alcohol and insoluble in water. Carbonic and the other acids dissolved it freely and alkalies precipitated it from the solution. Another body formed with the last had similar properties, but was insoluble in alcohol. The analyses of these three bodies gave the following results:—

	I.	II.	III.
Carbon	52.28	65.66	54.26
Hydrogen	6.38	6.05	5.34
Nitrogen	9.94	19.36	18.78
Oxygen	31.40	8.93	21.61

Similar substances to the above were formed when starch, mannite, cane sugar, or sugar of milk was heated with liquid ammonia in a sealed tube. When syrup was heated with liquid ammonia to 180° Centigrade, carbonate of ammonia, a black liquid and a black solid substance were formed, the two last of a very complex nature. The author speculates on the constitution of these bodies, admitting that he has but incompletely studied them. We do not, therefore, quote his speculations. He mentions a fact, however, which may be of value to some of our readers. A farmer, near Châlons, sprinkles his dung-heaps with ammoniacal gas liquor, and thereby obtains an excellent manure. The gas liquor used in this way producing a much better effect than when applied directly to the soil. M. Thenard examined the dung-heaps and found an abundance of fumic acid, or rather fumate of lime.

MISCELLANEOUS.

Popular Science.—A Mr. S. Holmes, writing to the *Mechanics' Magazine*, a weekly newspaper, which sometimes dabbles in science, favours its readers with the following piece of information:—"It is a proved fact, that the smoker's bugbear—nicotine—being an alkaloid, is instantly decomposed by the acid reaction of the saliva, and assumes the form of a harmless hydrocarburet." This reminds us of the celebrated definition of a lobster by the French *savans*; in two lines there are no less than four blunders—1, the saliva does not decompose nicotine; 2, it is not acid; 3, if it were, it would not form with nicotine a hydrocarburet; and 4, the compound it would form would not be harmless. The same paper, a few weeks ago, devoted an article to sneering at our statement that red-hot carbon decomposed aqueous vapour with formation of two inflammable gases.

The Polytechnic.—Return of Mr. Pepper.—The great services rendered to the cause of popular education by Mr. Pepper, and his untiring zeal in catering for the public amusement, during his former management of the Polytechnic, received a gratifying recognition on Monday evening, in the vast throng assembled to welcome him back to that Institution, and by whom his appearance on the platform of the large hall was hailed with the most enthusiastic plaudits. The subject chosen for the first of a new series of those popular scientific lectures which Mr. Pepper made so distinctive and pleasing a feature in the Polytechnic entertainments, was Ventilation, the discourse being one which, even without the lecturer's rare felicity of illustration and lucidity of explanation, would have been listened to with interest at this sultry season. The Polytechnic is certainly one of the best ventilated places of entertainment in the metropolis, as was shown by the comfortable temperature of the large hall on Monday, while crowded from floor to roof; but the difficulties which have hitherto rendered domestic ventilation unattainable, except by the rough expedient of opening the window, at the risk of the draught disarranging papers, covering furniture with dust, introducing a tormenting wasp, and probably catching cold, disposed every one to listen attentively to Mr. Pepper's exposition of the principles of ventilation, to feel interested in his ingenious experiments, and, we doubt not, to adopt the simple, inexpensive, and efficient apparatus which he recommended, and which has been patented by Mr. Cooke, C.E. The folds of wire gauze affixed to the upper sash prevent draughts by diffusing the current of air admitted, exclude dust and insects, effectually ventilate the apartment, and are easily fitted. After the lecture the auditory dispersed to view the pictures, sculptures, models, &c., so profusely displayed in the body of the building, and the ever attractive operations of the diver; and the entertainments concluded with the exhibition of a series of beautiful dissolving views, illustrative of a "Voyage down the Stream of Time," commencing with the rock-temple of Abou-Simbel, in Egypt, and terminating with the great fire at London Bridge.

ANSWERS TO CORRESPONDENTS.

Alchemy.—This is too often confounded with the search after the philosophers' stone and the gold-making of the sixteenth and seventeenth centuries. Alchemy was the science of chemistry, and included all those processes in which chemistry was technically applied. To the alchemists we owe modern chemistry and experimental philosophy.

Adulteration of Butter with Lard.—A correspondent wishes to know a ready means of detecting the presence of lard in butter, an adulteration which he is certain is almost universally practised with metropolitan "best fresh" and inferior qualities.

X. Y. Z.—Write to the Secretary, Dr. Odling, Burlington House, Piccadilly. He will give you the necessary information.

THE CHEMICAL NEWS.

VOL. IV. No. 93.—September 14, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.

(Continued from page 127.)

EVEN were the change which chloride of silver undergoes by the effect of daylight far smaller than it really is, it is quite clear that the estimation of silver by the moist way would yield incorrect results, if during the experiment discoloration were allowed to take place. It is therefore necessary to put all the bottles used during the experiment in cylindrical boxes made of some suitable metal, painted black inside, and to perform the experiment so that the light of the day can only have access to the bottles at the moment of observation, and even then the chloride of silver should not be quite uncovered, but the bottle be left in the metallic box, and a portion of the bottle only lifted out of the box sufficient to give space to inspect the supernatant liquid. When the bottles are to be shaken in the boxes, the necks of the former are covered with a suitable cover, or with a double cap made of black cloth, so as to expose nothing of the chloride of silver to the light during the operation of shaking. That the chloride of silver, when losing some of its chlorine, is really changed into the already-mentioned violet substance, may be readily shown, for if the bottle containing the chloride, is filled with chlorine gas it can be exposed to the daylight without discoloration.

When heated in a dry state, chloride of silver melts, it loses a little of its chlorine, and undergoes a similar change as when exposed to the light. All quantitative determinations, therefore, both of silver and chlorine, when made by heating and igniting the chloride of silver before weighing, yield a result which is a little below the truth. The white chloride of silver gets the more coloured the more chlorine is expelled. Chloride of silver is to a very great extent insoluble in water. If one-fifth part of a milligramme of silver in solution is added to 200 cubic centimètres of water, which are equal to 200,000 milligrammes, and there is then added as much common salt in solution as is equivalent to the silver, then it will be seen that the liquid is rendered blueish and milky. $\frac{1}{100000}$ th of silver can therefore be recognised as chloride of silver in water; this property is one of the most important in the estimation of silver by the moist way. Four times as much silver, however, is required to distinguish a precipitate. Nitric acid added to the last-mentioned liquid does not produce, as

far as can be seen, any diminution of the milkiness or of the precipitate. Chloride of silver, therefore, is not rendered more soluble in water by the presence of nitric acid. This fact, also, is of great importance for the estimation of silver by the moist way. Chloride of silver is rather, although even in small proportion, more soluble in strong nitric acid than in water. When 50 cubic centimètres of nitric acid of a specific gravity of 1.2 are taken, and one-twentieth part of a milligramme of silver is dissolved in this acid, and there is then added as much solution of common salt as is equivalent to that weight of silver, then the temporarily formed chloride of silver disappears. I will describe among the apparatus a dropping apparatus fit for such experiments. In the nitric acid solution mentioned in the last experiment, both nitrate of silver and common salt in solution can produce a trace of precipitate. When strong nitric acid, which contains suspended in an undissolved state a well visible trace of chloride of silver, is diluted with water, it is rendered perfectly clear. Chloride of silver, therefore, is soluble in a rather concentrated nitric acid, but it is still more soluble in nitric acid diluted with water.

Chloride of silver may be said to be equally little soluble in water as in weak nitric acid.

It is impossible to detect in either of these cases $\frac{1}{100000}$ th part of silver; $\frac{1}{100000}$ th may be detected in both cases: therefore, neither water nor weak nitric acid interfere with the estimation of silver by the moist way. But we have not only to deal, when actually experimenting, with the great insolubility of the chloride of silver, the question also presents itself at what degree of dilution a precipitate can be still perceptible. This may be put without any exaggeration at a dilution of one in 200,000 parts.

Chloride of silver is, to a certain extent, soluble in hydrochloric acid. In case hydrochloric acid is added to the water which contains, in a suspended state, the chloride of silver formed by $\frac{1}{100000}$ th part of metallic silver, then the milkiness formed by the precipitate disappears totally. Larger quantities of chloride of silver mixed through water are also dissolved by hydrochloric acid, and increasing temperature promotes this solvent property of hydrochloric acid. This goes on even to such an extent, that boiling concentrated hydrochloric acid dissolves a sufficient quantity of chloride of silver to make the latter precipitate on cooling in the form of octohedral crystals, the quantity of which increases on evaporation. Pierre (*Journ. de Pharm.* 3me Série, tome xii., p. 237) has found, that the solubility of chloride of silver in concentrated hydrochloric acid was about $\frac{1}{100}$ th, and in hydrochloric acid, diluted with twice its weight of water $\frac{1}{100}$ th. It may therefore give rise to some astonishment, when Otto (*Lehrbuch der Chemie*, Aufl. 3, bd. ii., abth. 2, s. 747) advises to precipitate a solution of a silver salt, wherein the quantity of silver has to be estimated, while warm, with hydrochloric acid; he even says to precipitate while the liquid is very warm, in order that, after shaking, the liquid may be rendered so

clear as to allow of decantation. In so doing, a weighable quantity of silver is lost. The idea given by Rose (*Analyt. Ch.*, ii., s. 199) is better, since he recommends to leave the liquid after having been warmed standing at rest for twelve hours, then to pour off the supernatant liquid, and to wash the chloride of silver with warm water.

It may be true that for all the usually-occurring cases in analytical chemistry the dilution with much water is sufficient to prevent hydrochloric acid to keep in solution the chloride of silver. It is equally true that even very much diluted hydrochloric acid has the property of dissolving minutely-divided chloride of silver to a visible extent.

Chloride of silver is not any more soluble in dilute sulphuric acid than it is in dilute nitric acid; sulphuric acid, therefore, may be quite as safely used for the dissolution of silver, as nitric acid, as far as this point is concerned.

Chloride of silver is, at a higher temperature, visibly soluble in a solution of tartaric acid; so much so, that a precipitate formed in the presence of tartaric acid at common temperature, disappears at boiling heat, but re-appears again on cooling.

Chloride of silver is soluble in all chlorides. In a quantity of one cubic centimetre of a concentrated aqueous solution of chloride of zinc, more than one milligramme of metallic silver may exist in solution without producing any turbidity at all. When diluted with water, chloride of silver makes its appearance.

The chlorides of sodium, potassium, calcium, barium, and strontium all dissolve some chloride of silver; an increased temperature increases the quantity of dissolved chloride of silver. On cooling cubical crystals are precipitated, which have been found to consist of double chlorides of silver and one of the mentioned metals.¹

The chlorides of magnesium, ammonium, and mercury (corrosive sublimate) do all dissolve some chloride of silver; chloride of mercury, however, does so to a small extent only.

The already-mentioned double chlorides do not bear the admixture of nitric acid; they are decomposed by it. It is therefore unnecessary to consider the presence of a double salt of chloride of silver and chloride of sodium in the estimation of silver by the moist way.

The nitrates of soda, potassa, lime, magnesia, and ammonia dissolve chloride of silver; this solubility is not great however at common temperature, but is so large in the heated, clear liquids, that they all become turbid on cooling by the precipitation of chloride of silver.

The solubility of chloride of silver in nitrate of soda will presently bring us to the explanation of a phenomenon which has a great influence on the estimation of silver by the moist way. Solutions of caustic potassa and soda and of carbonate of potassa and soda, do not decompose chloride of silver in suspension in a liquid at common temperature. On boiling such a liquid, chloride

of potassium and sodium are formed, as also oxide of silver. The best solvents for chloride of silver are liquid ammonia, cyanide of potassium, and the hyposulphites of potassa and soda. The two latter form well-known double salts.

The solution of chloride of silver in liquid ammonia, when exposed to the action of atmospheric air, deposits octahedral crystals of chloride of silver; when slightly warmed, shining scales are deposited; on boiling such a solution, detonating silver is formed. Acids precipitate from the solution of chloride of silver in ammonia chloride of silver. Nitrate of peroxide of mercury dissolves a large proportion of chloride of silver. The nitrates of most other metals are not endowed with this property. In every case it is so small as not to interfere with the estimation of silver in the moist way.

3. *Point of Neutrality and of Mutual Precipitation.*—I assume that to properly understand the following the reader is acquainted with the ordinary process of testing for silver by the moist way. The first question which immediately arises is, what quantity of the decimal solution of chloride of sodium has to be used after the addition of the standard solution of chloride of sodium? Suppose we had dissolved in nitric acid 1002 milligrammes of pure silver, and that 1000 milligrammes had been precipitated by the standard solution, 2 milligrammes have been left to be precipitated by the decimal solution of chloride of sodium. Let it further be supposed that the quantity of the decimal solution therefore required be added *guttatim*, 20 drops equal to 1 cubic centimetre, and that after every addition the liquor has been well shaken. At what moment is the addition of the decimal solution to cease?

I assume that the operator only adds the solution drop by drop, and shakes the liquid until clear again; that he can very clearly see that the bulk of the precipitate, formed after every addition of the decimal solution, diminishes, and that he comes at last to the certain conviction gradually, that after the addition of but one drop more, no precipitate would be any more obtained, the extreme limit of chemical accuracy has only then been reached: too much salt has not then been added. 100 cubic centimetres of the standard salt solution have precipitated 1000 milligrammes of pure silver; and assuming 20 drops to 1 cubic centimetre,² then every drop of the decimal salt solution has precipitated $\frac{1}{20}$ th milligramme of silver. Has everything been well and properly done, so that if 40 drops of the decimal solution had been required, we should have been justified in assuming the presence of 1002 milligrammes of silver?

This question requires a very accurate investigation, and the more so since, as far as I am aware from printed and published matter, it has never been fully gone into. The question itself is a general chemical one, and not merely a particular technical question only bearing upon the assay of silver, it is therefore a question of great scientific interest. It is almost unnecessary to mention that there is a very intimate relation between the right appreciation and solution of this question and the assay of silver; and it is equally needless to show that whatever bears upon the precipitation of silver, is applicable to all similar cases where precipitation takes place in general, and since the volumetrical method has justly become more and more general, and since precipitation is intimately connected with that process, I judged it best to treat this subject more minutely, also in a general chemical point of view, although I intend to pay most

¹ On account of the solubility of chloride of silver in common salt, or other chlorides of the metals of the alkalies, it is Rose's advice (*Analyt. Chem.*, ii., s. 198), when the presence of the said chlorides cannot be avoided, and when they are met with to a larger extent, to evaporate the liquid, after separation of the chloride of silver by filtration, nearly to dryness, and to add nitric acid, by which the chlorides are decomposed to nitrates, and to heat afterwards, so as to promote the precipitation of the small quantity of chloride of silver kept in solution by the chlorides. This is certainly a good plan, but it does not answer the purpose for which it is given completely, since chloride of silver, although less soluble in the nitrates which have been formed, than in an excess of chloride of sodium, for instance, is, however, kept in solution by the nitrates then present in the liquid to a very noticeable extent.

² In the part entitled the "Method" will be given the description, and some drawings of the necessary apparatus.

attention to that kind of analysis which bears upon silver, which, when well understood, may be taken as the type of the whole question.

When, to the clear and well-shaken liquid which has received 1002 parts of a solution of salt (and in which there is neither one drop too much, nor one too little of the decimal salt solution), a decimal solution of silver is added drop by drop, a precipitate is seen to make its appearance; if the liquid be shaken, and the precipitate be allowed to settle, then upon a fresh addition of more drops of the decimal solution of silver, another portion of precipitate will make its appearance. This precipitate diminishes after another addition of decimal solution of silver, and finally ceases to make its appearance when, at a temperature of from 15° to 17° C., 20 drops of decimal solution of silver have been added.

(To be continued.)

TECHNICAL CHEMISTRY.

Local Decomposition in Lead Aqueduct Pipes, by Mr. J. R. NICHOLS.

THE author calls attention to a source of danger attending the use of leaden pipes used for the conveyance of drinking-water which seems to have been hitherto disregarded. Even if it be admitted that the water which is supplied to the city of Boston from Lake Cochituate, like that of most New England ponds, be such that it may be safely used after having passed through lead pipe under ordinary circumstances, it would nevertheless be wrong to infer that this water can be employed with entire safety at all points of delivery, without first inquiring whether special conditions may not exist in some localities by which the character of the water may there be changed. Having observed several instances in which the inmates of a single house had suffered from lead disease induced by the use of aqueduct water, while the inhabitants of other parts of the city supplied with water from the same original source were unaffected, and having in one instance detected the presence of considerable quantities of lead in one of the cases first mentioned, while no reaction for lead could be obtained from a specimen of the same aqueduct water taken from another locality, the author proceeded to inquire into the cause which produces this lead impregnation in certain houses or districts while the general waters of a supply remain unaffected. He has noticed in the leaden pipes removed from cesspools, sinks, and wells, that the intensity of corrosive action had been in great measure confined to the sharpest bends and depressions in the pipe, while in some instances other portions remained intact. "I have in my possession," he says, "a section of supply pipe, removed from the aqueduct of a neighbouring city, in a portion of which corrosive action had proceeded so far as to cause leakage. The part thus acted upon was confined to an acute angle, and there is evidence to show that the plumber, in placing it in position, bent it in the wrong direction, thus creating the necessity for another turn in the opposite. This pipe had, doubtless, been subjected to two violent turns, which seriously impaired the homogeneity of the metal. An examination of lead pipe removed from buildings will certainly show that where there has been any perceptible amount of decomposition, it has been confined to the angles and depressions in its course. There are three causes or agencies which may perhaps

be sufficient to produce these results:—1. The disturbance in the crystalline structure of the metal by bending, whereby its electrical condition is changed and voltaic action promoted, giving rise to chemical decomposition. [Together with the galvanic action which must be induced wherever connections or faucets of copper, or alloy, are fastened to the leaden pipes, or where a crack or fissure in the latter has been filled with solder.] 2. The presence of organic matter, such as fragments of leaves, and impurities pervading all pond waters, and which may be detained in angles and depressions of the pipes. Their presence, undoubtedly, promotes oxidation (?) and the protoxide of lead will remain in solution, unless sufficient carbonic acid is furnished to change it. It is easy to conceive of conditions where this could not be the case. 3. Corrosions may be produced in lead pipes by the accidental presence of pieces of mortar. Where mortar is present, the lime would assist in oxidising the metal, and also aid in the solution of the oxide. Considerable portions of fresh mortar are frequently deposited in lead pipes during the erection of buildings. When the family commence the use of the water, it holds the salts of lead in solution, and its presence may be detected for months. The process of oxidation, which is retarded or prevented altogether by the presence of neutral salts in water, could not be materially interfered with under the conditions considered. It is obvious, if these observations and conclusions are correct, that much care should be exercised in placing pipes in position in buildings. In those leading to the culinary department, angles and depressions should be avoided. Violent twists and turns should not be permitted, and during the erection of houses, the open ends of protruding pipes should be carefully closed. Assuming the general fact that lead pipes, conveying the waters of our New England ponds, become coated and protected by an insoluble lead salt, the question arises, how long before this protection is secured, or, how soon may a family commence the use of water passing through new pipes with safety? In view of the manifest danger from local disturbances, the most sensible reply would be, *never*. A section of new lead pipe immersed in Cochituate water one hour, at a temperature of 65° F., gave a decided lead reaction with sulphydric acid. Removed and placed in six fresh portions of water, one hour in each, the waters, when tested, gave similar results. The experiment continued during two weeks. Varying the time of immersion in fresh portions of water from one to ten hours, the lead indications continued, although at last feeble. These results are sufficient to show that individuals or families should not commence the use of water flowing through new pipet until considerable time has elapsed, and much water contact secured."—*Boston Medical and Surgical Journal*, lxiii. 149.

PHARMACY, TOXICOLOGY, &c.

On a New Anæsthetic, Kerosolene, by EPHRAIM CUTTER, M.D., of Woburn, Mass., U.S.

THIS new anæsthetic, kerosolene, is obtained as a product, which hitherto has been thrown away as useless, in the manufacture of kerosene oil, by the destructive distillation of coal, not coal-oil nor tar. If I understand it aright, the crude volatile matters that come over from the still at a temperature of 150° Fahrenheit are condensed and treated with sulphuric acid and then redi-

titled. The result is the article you see before you. It may be largely produced. I am informed that from forty to sixty thousand gallons could be annually made by one establishment alone in Boston from the waste of the usual course of manufacture for that period. It could be furnished at a dollar a gallon.

The chemistry of the article has not been described. It has been named by the discoverers Kerosolene or Keroform, possibly under the impression that it may be a new organic radical, or a compound of a new organic radical. Whether this has been definitely determined by analysis is not known. From its mode of production, specific gravity, physical and physiological properties, one would fain class it as an ether or an analogous hydrocarbon. Kerosolene is a beautiful colourless and volatile liquid, with a specific gravity of .634 (roughly determined). Ether has a specific gravity of about .750, chloroform 1.49. Tested with litmus paper, it was found neutral. As regards the appearance to the sight, it cannot be distinguished from ether. The odour is not peculiar and hardly perceptible, and what is perceptible is very pleasant, resembling that of chloroform. It leaves no persistent smell in the apartment where it is evaporated. In this respect it is very much superior to ether, and is not so sickish as chloroform. It is tasteless. It evaporates wholly on exposure. A given quantity of ether and kerosolene was evaporated in capsules floating in water at a temperature of 108° F. The ether disappeared first. It is highly inflammable. Besides the odour just mentioned, there is a faint smell, like kerosene-oil. It seems as if the specimen examined was not chemically pure, but contaminated with a small quantity of the kerosene-oil. (The different samples seen have varied, some in regard to this kerosene odour. The second sample contained much more than the first, and occasioned a slight headache upon inhalation, which a third did not, having very much less of the kerosene odour.) This suspicion is confirmed by agitating the kerosolene with twice its bulk of water. The phenomena witnessed are the same as are seen when ether is similarly treated, only that the kerosolene forms larger and more persistent balls, and the water is much more and longer turbid. A portion allowed to stand twelve hours after agitation with the water presented a distinct layer of oily matter, between the upper surface of the water and the lower surface of the kerosolene. Ether furnished a similar one, but not so distinct and voluminous.

The vapour applied to the skin, as is sometimes done with chloroform in neuralgia, is irritating, but not to the same degree as that of the latter. The first intimation that this substance had anæsthetic properties, was declared by the fact that an Irishman, sent in to clean out a still, became totally insensible. Upon being withdrawn, and recovering his faculties, he expressed himself as having had a very fine "dhrame." The article was thus suspected: a quantity of it was procured, and given to mice and flies. One mouse was killed by it. Mr. W. B. Merrill, an *attaché* of the Works (Downer Kerosene-Oil Company, Boston), then introduced it to the notice of Dr. H. J. Bowditch, who in turn called the attention of the Boston Society of Medical Improvement to it. This body appointed a commission to examine into its claims. In prosecuting their inquiries Dr. H. J. Biglow was probably the first to try it upon the human subject, and that subject was himself. He also exhibited it to some patients. An account of his experiments was published in the *Boston Medical and Surgical Journal*.

The writer has experimented upon himself and others. In my own case, it was given to me by my friend and student, Mr. S. W. Abbott. I remained under its influence full half-an-hour twice. Perhaps four ounces of the kerosolene were consumed in each trial. The first impression is sudden, powerful, and pleasant. Almost immediately I passed into a state of pleasurable insensibility, which at no time was perfect. At least there would be responses to the pricks of a pin, and the muscles were not quiet—although afterwards I had no recollection of any such thing. The pulse and respiration were not much altered from their normal rate, the face was rather pale. At the first trial, Mr. Abbott states that I travelled about and grasped the napkin on which the kerosolene was found with my teeth, so strongly that he could hardly get it away. The stimulus of the vapour penetrated the whole frame, even to the tips of the fingers. No unpleasant effects have been experienced from the two experimentations, except a slight headache, which I think may be due to the presence of the adventitious kerosolene.

As you breathe the vapour, you seem to float away into a wavy maze, with a sense of complete loneliness. There appears to be but one object in the universe, and that object is yourself. On recovery, the first thing seen is deemed the next only existence in the universe. It takes some little time to regain all the faculties.

At the meeting at which the above was read, quantities of the kerosolene were distributed, and several of the gentlemen of the Society inhaled it in the presence of the assembled company. They came under its influence immediately, and also recovered from it well. Dr. Ingalls reported two trials of its external use in cases of neuralgia, in one of which it succeeded. The mode of procedure is to moisten a pledget of cotton wool with the kerosolene, lay it upon the skin, and cover it with a watch crystal.

From the above trials it is proper to infer that kerosolene is a very fit article for further experiment. It must be presumed to be almost safe, as in all the trials of it upon man and the lower animals, only a mouse has been killed. Its price, odour, and instantaneousness of action are advantages over ether.—*American Medical Times*.

PHYSICAL SCIENCE.

Notes on the Atmospheric Lines of the Solar Spectrum, and on certain Spectra of Gases, by Dr. JOHN HALL GLADSTONE, F.R.S.

IN the paper of Sir David Brewster and myself on the lines of the solar spectrum¹, attention was drawn to the following among other phenomena:—

1st. "When the sun descends towards the horizon and shines through a rapidly increasing depth of air, certain lines which before were little if at all visible, became black and well defined, and dark bands appear even in what were formerly the most luminous parts of the spectrum." These we termed "atmospheric lines." We did not wish to express by that term anything beyond the fact above mentioned; yet we threw out the idea that these lines may have their origin "in the air that encircles our globe."

2nd. In the case of those artificial flames whose spectra "consist of a series of luminous bands separated

¹ *Philosophical Transactions*, 1860, p. 149.

by dark spaces. . . . These luminous bands sometimes coincide with the dark lines of the solar spectrum."

About the same time Kirchhoff² published his theory that this remarkable coincidence is due to the presence in the atmosphere of the sun of the substances which emit these luminous bands, and their appearance as dark lines is because "the spectrum of an incandescent gas becomes reversed, when a source of light of sufficient intensity, giving a continuous spectrum, is placed behind the luminous gas." It also appears that "sodium vapour at a temperature much below that at which it becomes luminous, exerts its absorptive power at exactly the same point of the spectrum as it does at the highest temperatures which we can produce." It is, however, as yet an undetermined question at what temperature below that at which it becomes luminous, a gas ceases to absorb; though, from the close connection which has been shown to exist between emission and absorption, there can be little doubt that such a limit would be arrived at.

This theory of the origin of Fraunhofer's lines, and the uncertainty just alluded to, suggested the desirableness of comparing the "atmospheric lines" of absorption with the luminous bands which make their appearance in the linear spectra of the light emitted by the different constituents of the atmosphere when sufficiently heated. If all the rays emitted by these different constituents should be found to coincide with the "atmospheric lines," it would show at once the origin of the lines, and prove that gases at the ordinary temperature will absorb rays of the same refrangibility as those they emit when themselves glowing. If, on the contrary, they should be found not to coincide, it would prove by an extreme case (for we operate thus upon many miles of oxygen and nitrogen gases at least) that this connection between absorption and emission either does not extend to these elements, or is confined within those narrower limits of temperature which theory seems to require. It was also conceivable that the atmospheric lines might coincide with the rays emitted, not by all, but by a portion of the constituents of the atmosphere.

The following data exist for this comparison:—Angstrom³ has delineated the luminous bands due to the gas when the electric spark is sent through nitrogen, oxygen, carbonic acid, hydrogen, &c. Plücker⁴ has described and measured those bands which appear in the spectra of the same and other gases when they serve as the residuary gas in Geissler's tubes. Under the influence of the electric discharge, the vapour of water, carbonic acid, ammonia, and other compounds are decomposed; but it occurred to me that the oxyhydrogen flame must consist partly, if not entirely, of glowing steam, since it is only when the two elements combine that the heat is evolved; and that similarly the flame of carbonic oxide burning in air must contain the light emitted from glowing carbonic acid. I therefore subjected these two flames to prismatic examination.

The result of the comparison has been that not one of these observations shows any accordance between the luminous bands due to the gas, and the dark lines that make their appearance in the solar spectrum when the sun is shining through a great depth of air. Hydrogen alone is inconclusive. Neither is there any accordance between these luminous bands and the more prominent lines of ordinary solar spectrum.

This shows that oxygen and nitrogen, and perhaps other gases, though in enormous quantity, do not absorb at the ordinary temperature rays of the same refrangibility as those they emit when heated by the means specified.

It would not be legitimate to infer from this that the atmospheric lines have not their origin in the absorbent power of one or more of the common constituents of the atmosphere. It is well known that some gases when placed before a continuous spectrum produce lines of absorption; among these are bromine and iodine vapour; yet the dark lines caused by these two halogens⁵ do not coincide with the bright lines into which Plücker found the light of Geissler's tubes containing bromine and iodine to be resolved by the prism; nor have I succeeded in reversing them by bringing these substances into a very hot but little luminous flame. Bright lines were discerned, but in other positions. In connection with this subject, it may be worth noting that a prismatic examination of the sun's rays passing through three inches of mercury vapour at above 300° C., did not afford the least indication of the reversal of the bright rays that appear when that metal is rendered incandescent.

From the fact that the atmospheric lines do not always present the same appearance when the sun is on the horizon, and that the band δ has been observed during a shower, and the most prominent lines during a fog, it has been sometimes supposed that the aqueous vapour in the atmosphere is the cause of them. Yet this can scarcely be. They seem not to be due to little vesicles of condensed vapour; for the sun's rays, when passing through the edges of a cloud, do not exhibit them, unless, of course, near the horizon. And they seem not to be due to gaseous water; for they appear near sunset when the aqueous vapour in the atmosphere is reduced to a minimum by frosty weather, though they are not seen when the sun is higher up in the heavens on a damp warm day. From Sir David Brewster's notes, it appears that February 10, 11, 12, and 13 of the year 1838 were frosty days; yet the lines were well seen: δ , ϵ , η , C 6, C 15, C 16, and D are specially mentioned. On the 13th, when the thermometer stood at 23° F., ϵ is said to have been the most prominent.

In the paper referred to at the commencement, we, in common with most of those who worked on the subject before the appearance of Kirchhoff and Bunsen's paper⁶, ascribed a bright line coincident with D to other spectra than that of soda. This was no doubt owing to the almost universal trace of that substance.

The electric lights produced between charcoal points by Professor Holmes's magneto-apparatus, and by a galvanic battery with M. Serin's lamp, were found to be identical, when subjected to prismatic analysis. Each exhibited a continuous spectrum, and not those variations of bright and dark which other observers, as well as myself, have noticed in electric lights from charcoal points of but inferior quality. The spectrum extended at both ends beyond that of ordinary direct sunlight, and the only lines which I could discern were bright ones in the violet or lavender region. The following refractive indices were determined for the magneto-electric light; and they are compared with the refractive indices of the nearest principal dark lines of the solar spectrum as determined with the same prism. The relative position

of these bright rays and the dark lines in the lavender part of the spectrum, which are only visible in the sun's light under the most favourable circumstances, must not be relied on as accurate, since it was determined by measurement, and not by direct comparison. Possible inaccuracy of adjustment will render the fourth place of decimals quite uncertain. The remarkable extension of the spectrum of this electric light, both at the red and violet ends, is, however, indisputable.

PROCEEDINGS OF SOCIETIES.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE Thirty-first Annual Meeting of this Association commenced on Wednesday, September 4, at Manchester, under the direction of the following officers:—

President.—William Fairbairn, Esq., LL.D., C.E., F.R.S.

Vice-Presidents.—The Earl of Ellesmere, F.R.G.S.; the Lord Stanley, M.P., D.C.L., F.R.G.S.; the Lord Bishop of Manchester, D.D., F.R.S., F.G.S.; Sir Philip de Malpas Grey Egerton, Bart., M.P., F.R.S., F.G.S.; Sir Benjamin Heywood, Bart., F.R.S.; Thomas Bazley, Esq., M.P.; James Aspinall Turner, Esq., M.P.; James Prescott Joule, Esq., LL.D., F.R.S., President of the Literary and Philosophical Society of Manchester; Joseph Whitworth, Esq., F.R.S., M. Inst. C.E.

General Secretary.—Rev. Robert Walker, M.A., F.R.S., Professor of Experimental Philosophy, Oxford.

Assistant General Secretary.—John Phillips, Esq., M.A., LL.D., F.R.S., F.G.S., Professor of Geology, Oxford.

General Treasurer.—John Taylor, Esq., F.R.S.

Local Secretaries.—Robert Dukinfield Darbishire, Esq., B.A., F.G.S., 21, Brown Street, Manchester; Alfred Neild, Esq., Mayfield, Manchester; Arthur Ransome, Esq., M.A., St. Peter's Square, Manchester; Professor Henry Enfield Roscoe, B.A., Owens College, Manchester.

Local Treasurer.—Robert Phillips Greg, Esq., F.G.S., Manchester.

The Council met at ten o'clock in the morning, and at one o'clock the General Committee held its first meeting in the Town-hall, for the election of sectional officers and the despatch of business.

The first general meeting of the Association was held in the Free Trade Hall, at eight p.m., when at a few minutes after eight Lord WHORRESELEY, the retiring President, took the chair amid loud cheers. He said:—

Ladies and Gentlemen,—In retiring from the office I have had the honour to hold, it is a great pleasure to me to know that I am to be succeeded by one who is so well worthy of your support. We may derive important instruction from the career of Mr. Fairbairn, whether we view him as the successful engineer, or as a distinguished man of science. In the former capacity he is one who has, by perseverance combined with talent, risen from small beginnings to the summit of his profession, and he forms one of that noble class of men, the Stephansons, the Brunels, the Whitworths, the Armstrongs, which have conferred such important

services on their country, and some of whom, unfortunately for that country, have perished, alas, too soon, exhausted by their arduous toils. Mr. Fairbairn is, therefore, one of the many examples of what can be done in England by such men, who resolve, undaunted by the difficulties and obstructions that beset their path, to struggle gallantly onward till success crown their efforts. Again, if we look at Mr. Fairbairn's claims to scientific distinction, they read to us an important lesson; for they show what can be done by zeal and energy, and the exercise of a strong and resolute will, fully determined to carry out objects in which the public is deeply interested. It is extraordinary that any man should have been able during the few leisure hours that can be snatched from an important and engrossing business, to accomplish for science what Mr. Fairbairn has done; and not only has he been a most successful contributor to mechanical science, but his liberality has been unbounded in placing all his great mechanical resources at the disposal of his fellow-labourers in the same field. Well and truly was it said when the Royal medal was conferred on Mr. Fairbairn for his researches:—"Perhaps there is scarcely a single individual living who has made so many careful experimental inquiries on subjects of primary importance to the commercial and manufacturing interests of the country, and has so liberally contributed them to the world." Such a man is one whom all should delight to honour. And to such a man I resign, with great satisfaction, the chair which I now vacate.

Mr. FAIRBAIRN then took the chair amid loud cheers. He spoke as follows:—

Gentlemen of the British Association,—Ever since my election to the high office I now occupy I have been deeply sensible of my own unfitness for a post of so much distinction and responsibility; and when I call to mind the illustrious men who have preceded me in this chair, and see around me so many persons much better qualified for the office than myself, I feel the novelty of my position and unfeigned embarrassment in addressing you. I should, however, very imperfectly discharge the duties which devolve upon me, as the successor of the distinguished nobleman who presided over the meetings of last year, if I neglected to thank you for the honourable position in which you have placed me, and to express at the outset my gratitude to those valued friends with whom I have been united for many years in the labours of the Sections of this Association, and from whom I have invariably received every mark of esteem.

A careful perusal of the history of this Association will demonstrate that it was the first, and for a long time the only institution, which brought together for a common object the learned Professors of our Universities and the workers in practical science. These periodical *réunions* have been of incalculable benefit in giving to practice that soundness of principle and certainty of progressive improvement which can only be obtained by the accurate study of science and its application to the arts. On the other hand, the men of actual practice have reciprocated the benefits thus received from theory, in testing by actual experiment deductions which were doubtful, and rectifying those which were erroneous. Guided by an extended experience, and exercising a sound and disciplined judgment, they have often corrected theories apparently accurate, but nevertheless founded on incomplete data or on false assumptions inadvertently introduced. If the British Association had effected nothing more than the removal of the anomalous separation of theory and practice, it would have gained imperishable renown in the benefit thus conferred. Were I to enlarge on the relation of the achievements of science to the comforts and enjoyments of man, I should have to refer to the present epoch as one of the most important in the history of the world. At no former period did science contribute so much to the uses of life and the wants of society. And in doing this it has only been fulfilling that mission which Bacon, the great father of modern science, appointed for it, when he wrote that "the legitimate goal of the sciences is the endowment of human life with new inventions and riches," and when he sought for a natural philosophy which, not spending its energy on barren disquisitions, "should be operative for the benefit and endowment of mankind." Looking, then, to the fact that, while in our time all the sciences have yielded this fruit, engineering science, with which I have been most intimately connected, has pre-eminently advanced the power, the wealth, and the

comforts of mankind, I shall probably best discharge the duties of the office I have the honour to fill by stating, as briefly as possible, the more recent scientific discoveries which have so influenced the relations of social life. I shall, therefore, not dwell so much on the progress of abstract science, important as that is, but shall rather endeavour briefly to examine the application of science to the useful arts, and the results which have followed, and are likely to follow, in the improvement of the condition of society.

The history of man throughout the gradations and changes which he undergoes in advancing from a primitive barbarism to a state of civilization shows that he has been chiefly stimulated to the cultivation of science and the development of his inventive powers by the urgent necessity of providing for his wants and securing his safety. There is no nation, however barbarous, which does not inherit the germs of civilization, and there is scarcely any which has not done something towards applying the rudiments of science to the purposes of daily life. Among the South Sea Islanders, when discovered by Cook, the Applied Sciences—if I may use the term—were not entirely unknown. They had observed something of the motions of the heavenly bodies, and watched with interest their revolutions, in order to apply this knowledge to the division of time. They were not entirely deficient in the construction of instruments of husbandry, of war, and of music. They had made themselves acquainted with the rudiments of ship-building and navigation in the construction and management of their canoes. Out off from the influence of European civilization, and deprived of intercourse with higher grades of mind, we still find the inherent principle of progression exhibiting itself, and the inventive and reasoning powers developed in the attempt to secure the means of subsistence. Again, if we compare man as he exists in small communities with his condition where large numbers are congregated together, we find that densely-populated countries are the most prolific in inventions, and advance most rapidly in science. Because the wants of the many are greater than those of the few, there is a more vigorous struggle against the natural limitations of supply, a more careful husbanding of resources, and there are more minds at work. This fact is strikingly exemplified in the history of Mexico and Peru; and its attestation is found in the numerous monuments of the past which are seen in Central America, where the remains of cities and temples, and vast public works, erected by a people endowed with high intellectual acquirements, can still be traced. There have been discovered a system of canals for irrigation; long mining galleries cut in the solid rock in search of lead, tin, and copper; pyramids not unlike those of Egypt; earthenware vases and cups, and manuscripts containing the records of their history; all testifying to so high a degree of scientific culture and practical skill that, looking at the cruelties which attended the conquests of Cortes and Pizarro, we may well hesitate as to which had the stronger claims on our sympathy, the victors or the vanquished.

In attempting to notice those branches of science with which I am but imperfectly acquainted, I shall have to claim your indulgence. This Association, as you are aware, does not confine its discussions and investigations to any particular science; and one great advantage of this is, that it leads to the division of labour, while the attention each department receives, and the harmony with which the plan has hitherto worked, afford the best guarantee of its wisdom and proof of its success. In the early history of Astronomy, how vague and unsatisfactory, were the wild theories and conjectures which supplied the place of demonstrated physical truths and carefully observed laws! How immeasurably small, what a very speck, does man appear, with all the wonders of his invention, when contrasted with the mighty works of the Creator; and how imperfect is our apprehension, even in the highest flights of poetic imagination, of the boundless depths of space! These reflections naturally suggest themselves in the contemplation of the works of an Almighty Power, and impress the mind with a reverential awe of the great Author of our existence. The great revolution which laid the foundation of modern astronomy, and which, indeed, marks the birth of modern physical science, is chiefly due to three or four distinguished philosophers. Tycho Brahe, by his system of accurate measurement of the positions of the heavenly bodies; Copernicus, by his history of the solar system; Galileo, by the application of the telescope; and Kepler, by the discovery of the laws of the planetary motions, all assisted in advancing, by prodigious strides, towards a

true knowledge of the constitution of the universe. It remained for Newton to introduce, at a later period, the idea of an attraction varying directly as the mass, and inversely as the square of the distance, and thus to reduce celestial phenomena to the greatest simplicity, by comprehending them under a single law. Without tracing the details of the history of this science, we may notice that in more recent times astronomical discoveries have been closely connected with high mechanical skill in the construction of instruments of precision. The telescope has enormously increased the catalogue of the fixed stars, or those "landmarks of the universe," as Sir John Herschel terms them, "which never deceive the astronomer, navigator, or surveyor." The number of known planets and asteroids has also been greatly enlarged. The discovery of Uranus resulted immediately from the perfection attained by Sir William Herschel in the construction of his telescope. More recently, the structure of the nebulae has been unfolded, through the application to their study of the colossal telescope of Lord Rosse. In all these directions much has been done, both by our present distinguished Astronomer Royal and also by amateur observers in private observatories, all of whom, with Mr. Lassells at their head, are making rapid advances in this department of physical science. Our knowledge of the physical constitution of the central body of our system seems likely, at the present time, to be much increased. The spots on the sun's disc were noticed by Galileo and his contemporaries, and enabled them to ascertain the time of its rotation and the inclination of its axis. They also correctly inferred, from their appearance, the existence of a luminous envelope, in which funnel-shaped depressions revealed a solid and dark nucleus. Just a century ago, Alexander Wilson indicated the presence of a second and less luminous envelope beneath the outer stratum; and his discovery was confirmed by Sir William Herschel, who was led to assume the presence of a double stratum of clouds, the upper intensely luminous, the lower grey, and forming the penumbra of the spots. Observations during eclipses have rendered probable the supposition that a third and outermost stratum of imperfect transparency incloses concentrically the other envelopes. Still more recently, the remarkable discoveries of Kirchhoff and Bunsen require us to believe that a solid or liquid photosphere is seen through an atmosphere containing iron, sodium, lithium, and other metals in a vaporous condition. We must still wait for the application of more perfect instruments, and especially for the careful registering of the appearances of the sun by the photeliograph of Sir John Herschel, so ably employed by Mr. Warren De La Rue, Mr. Welsh, and others, before we can expect a solution of all the problems thus suggested. Guided by the same principles which have been so successful in astronomy, its sister science, Magnetism, emerging from its infancy, has of late advanced rapidly in that stage of development which is marked by assiduous and systematic observation of the phenomena, by careful analysis and presentation of the facts which they disclose, and by the grouping of these in generalisations, which, when the basis on which they rest shall be more extended, will prepare the way for the conception of a general physical theory, in which all the phenomena shall be comprehended, while each shall receive its separate and satisfactory explanation. It is unnecessary to remind you of the deep interest which the British Association has at all times taken in the advancement of this branch of natural knowledge, or of the specific recommendations which, made in conjunction with the Royal Society, have been productive of such various and important results. To refer but to a single instance: we have seen those magnetic disturbances, so mysterious in their origin and so extensive in simultaneous prevalence,—and which, less than twenty years ago, were designated by a term specially denoting that their laws were wholly unknown,—traced to laws of periodical recurrence, revealing, without a doubt, their origin in the central body of our system, by inequalities which have for their respective periods the solar day, the solar year, and, still more remarkably, and until lately unsuspected, solar cycle of about ten of our terrestrial years, to whose existence they bear testimony in conjunction with the solar spots; but whose nature and causes are in all other respects still wrapped in entire obscurity. We owe to General Sabine, especially, the recognition and study of these and other solar magnetic influences, and of the magnetic influence of the moon similarly attested by concurrent determinations in many parts of the globe, which are now held to constitute a distinct branch of this

science, not inappropriately named "celestial," as distinguished from purely terrestrial magnetism.

We ought not in this town to forget that the very rapid advance which has been made in our time in Chemistry is due to the law of equivalents, or Atomic Theory, first discovered by our townsman, John Dalton. Since the development of this law, its progress has been unimpeded, and it has had a most direct bearing on the comforts and enjoyments of life. A knowledge of the constituents of food has led to important deductions as to the relative nutritive value and commercial importance of different materials. Water has been studied in reference to the deleterious impurities with which it is so apt to be contaminated in its distribution to the inhabitants of large towns. The power of analysis, which enables us to detect adulterations, has been invaluable to the public health, and would be much more so if it were possible to obviate the difficulties which have prevented the operation of recent legislation on this subject. We have another proof of the utility of this science in its application to medicine; and the estimation in which it is held by the medical profession is the true index of its value in the diagnosis and treatment of disease. The largest developments of chemistry, however, have been in connexion with the useful arts. What would now be the condition of calico printing, bleaching, dyeing, and even agriculture itself, if they had been deprived of the aid of theoretic chemistry? For example, aniline—first discovered in coal tar by Dr. Hoffman, who has so admirably developed its properties—is now most extensively used as the basis of red, blue, violet, and green dyes. This important discovery will probably in a few years render this country independent of the world for dye stuffs; and it is more than probable that England, instead of drawing her dye stuffs from foreign countries, may herself become the centre from which all the world will be supplied. It is an interesting fact that at the same time, in another branch of this science, M. Tournet has lately demonstrated that the colours of gems, such as the emerald, aquamarine, amethyst, smoked rock-crystal, and others, are due to volatile hydro-carbons, first noticed by Sir David Brewster in clouded topaz, and that they are not derived from metallic oxides, as has been hitherto believed. Another remarkable advance has recently been made by Bunsen and Kirchhoff in the application of the coloured rays of the prism to analytical research. We may consider their discoveries as the commencement of a new era in analytical chemistry, from the extraordinary facilities they afford in the qualitative detection of the minutest traces of elementary bodies. The value of this method has been proved by the discovery of the new metals, cesium and rubidium, by M. Bunsen; and it has yielded another remarkable result in demonstrating the existence of iron and six other known metals in the sun. In noticing the more recent discoveries in this important science, I must not pass over in silence the valuable light which chemistry has thrown upon the composition of iron and steel. Although Despretz demonstrated many years ago that iron would combine with nitrogen, yet it was not until 1857 that Mr. C. Binks proved that nitrogen is an essential element of steel; and more recently M. Caron and M. Frémy have further elucidated this subject; the former showing that cyanogen, or cyanide of ammonium, is the essential element which converts wrought iron into steel; the latter combining iron with nitrogen through the medium of ammonia, and then converting it into steel by bringing it at the proper temperature into contact with common coal gas. There is little doubt that in a few years these discoveries will enable Sheffield manufacturers to replace their present uncertain, cumbersome, and expensive process by a method at once simple and inexpensive, and so completely under control as to admit of any required degree of conversion being obtained with absolute certainty. Mr. Grace Calvert, also, has proved that cast iron contains nitrogen, and has shown that it is a definite compound of carbon and iron, mixed with various proportions of metallic iron, according to its nature. Before leaving chemical science, I must refer to the interesting discovery by M. Deville, by which he succeeded in rapidly melting thirty-eight or forty pounds of platinum—a metal till then considered almost infusible. This discovery will render the extraction of platinum from the ore more perfect, and, by reducing its cost, will greatly facilitate its application to the arts.

It is little more than half a century since Geology assumed the distinctive character of a science. Taking into consideration the aspects of Nature in different epochs of the history

of the earth, it has been found that the study of the change at present going on in the world around us enables us to understand the past revolutions of the globe, and the conditions and circumstances under which strata have been formed, and organic remains embedded and preserved. The geologist has increasingly tended to believe that the changes which have taken place on the face of the globe, from the earliest times to the present, are the result of agencies still at work. But, while it is his high office to record the distribution of life in past ages, and the evidence of physical changes in the arrangement of land and water, his results hitherto have indicated no traces of its beginning, nor have they afforded evidence of the time of its future duration. Geology has been indebted for this progress very largely to the investigations of Sedgwick and the writings of Sir Charles Lyell. As an example of the application of geology to the practical uses of life, I may cite the discovery of the gold-fields of Australia, which might long have remained hidden but for the researches of Sir Roderick Murchison in the Ural Mountains on the geological position of the strata from which the Russian gold is obtained. From this investigation he was led by inductive reasoning to believe that gold would be found in similar rocks, specimens of which had been sent him from Australia. The last years of the active life of this distinguished geologist have been devoted to the re-examination of the rocks of his native highlands of Scotland. Applying to them those principles of classification which he long since established, he has demonstrated that the crystalline limestone and quartz rocks which are associated with mica schists, &c., belong by their embedded organic remains to the Lower Silurian rocks. Descending from this well-marked horizon, he shows the existence beneath all such fossiliferous strata of vast masses of sand-stone and conglomerate of Cambrian age; and, lastly, he has proved the existence of a fundamental gneiss, on which all the other rocks repose, and which, occupying the north-west Hebrides, and the west coasts of Sutherland and Ross, is the oldest rock formation on the British Isles, it being unknown in England, Wales, or Ireland.

It is well known that the temperature increases as we descend through the earth's crust, from a certain point near the surface, at which the temperature is constant. In various mines, borings, and artesian wells the temperature has been found to increase about one degree Fahrenheit for every sixty or sixty-five feet of descent. In some carefully conducted experiments during the sinking of Dukinfield Deep Mine—one of the deepest pits in this country—it was found that a mean increase of about one degree in seventy-one feet occurred. If we take the ratio thus indicated, and assume it to extend to much greater depths, we should reach at two and a-half miles from the surface, strata at the temperature of boiling water; and at depths of about fifty or sixty miles the temperature would be sufficient to melt, under the ordinary pressure of the atmosphere, the hardest rocks. Reasoning from these facts, it would appear that the mass of the globe, at no great depth, must be in a fluid state. But this deduction requires to be modified by other considerations, namely, the influence of pressure on the fusing point and the relative conductivity of the rocks which form the earth's crust. To solve these questions a series of important experiments were instituted by Mr. Hopkins, in the prosecution of which Dr. Joule and myself took part; and after a long and laborious investigation it was found that the temperature of fluidity increased about one degree Fahrenheit for every five hundred pounds of pressure in the case of spumaeeti, bees'-wax, and other similar substances. However, on extending these experiments to less compressible substances, such as tin and barytes, a similar increase was not observed. But this series of experiments has been unavoidably interrupted; nor is the series on the conductivity of rocks entirely finished. Until they have been completed by Mr. Hopkins, we can only make a partial use of them in forming an opinion of the thickness of the earth's solid crust. Judging, however, alone from the greater conductivity of the igneous rocks, we may calculate that the thickness cannot possibly be less than nearly three times as great as that calculated on the usual suppositions of the conductive power of the terrestrial mass at enormous depths being no greater than that of the superficial sedimentary beds. Other modes of investigation which Mr. Hopkins has brought to bear on this question appear to lead to the conclusion that the thickness of the earth's crust is much greater even than that above stated. This would require us to assume that a part of the

heat in the crust is due to superficial and external rather than central causes. This does not bear directly against the doctrine of central heat, but shows that only a part of the increase of temperature observed in mines and deep wells is due to the outward flow of that heat.

Touching those highly interesting branches of science, Botany and Zoology, it may be considered presumptuous in me to offer any remarks. I have, however, not entirely neglected, in my earlier days, to inform myself of certain portions of natural history, which cannot but be attractive to all who delight in the wonderful beauties of natural objects. How interesting is the organization of animals and plants! how admirably adapted to their different functions and spheres of life! They want nothing, yet have nothing superfluous. Every organ is adapted perfectly to its functions; and the researches of Owen, Agassiz, Darwin, Hooker, Daubeny, Babington, and Jardine, fully illustrate the perfection of the animal and vegetable economy of nature.

Two other important branches of scientific research, Geography and Ethnology, have for some years been united, in this Association, in one section, and that probably the most attractive and popular of them all. We are much indebted to Sir Roderick Murchison, among other members of the Association, for its continued prosperity, and the high position it has attained in public estimation. The spirit of enterprise, courage and perseverance displayed by our travellers in all parts of the world have been powerfully stimulated and well supported by the Royal Geographical Society; and the prominence and rapid publicity given to discoveries by that body have largely promoted geographical research. In Physical Geography, the late Baron von Humboldt has been one of the largest contributors, and we are chiefly indebted to his personal researches and numerous writings for the elevated position it now holds among the sciences. To Humboldt we owe our knowledge of the physical features of Central and Southern America. To Parry, Sir James Ross and Scoresby we are indebted for discoveries in the Arctic and Antarctic regions. Geography has also been advanced by the first voyage of Franklin down the Copper Mine River, and along the inhospitable shores of the Northern Seas, as far as Point Turnagain; as also by that ill-fated expedition in search of a North-West passage, followed by others in search of the unfortunate men who perished in their attempt to reach those ice-bound regions, so often stimulated by the untiring energy of a high-minded woman. In addition to these, the discoveries of Dr. Livingstone in Africa have opened to us a wide field of future enterprise along the banks of the Zambesi and its tributaries. To these, we may add the explorations of Captain Burton in the same continent, and those also by Captain Speke and Captain Grant of a hitherto unknown region, in which it has been suggested that the White Nile has its source, flowing from one of two immense lakes, upwards of 300 miles long by 100 broad, and situated at an elevation of 4000 feet above the sea. To these remarkable discoveries I ought to add an honourable mention of the sagacious and perilous exploration of Central and Northern Australia by Mr. McDouall Stuart.

Having glanced, however imperfectly, at some of the most important branches of science which engage the attention of Members of this Association, I would now invite attention to the Mechanical Sciences, with which I am more familiarly acquainted. They may be divided into Theoretical Mechanics and Dynamics, comprising the conditions of equilibrium and the laws of motion; and Applied Mechanics, relating to the construction of machines. I have already observed that Practice and Theory are twin sisters, and must work together to ensure a steady progress in mechanical art. Let us, then, maintain this union as the best and safest basis of national progress, and, moreover, let us recognise it as one of the distinctive aims of the annual *réunions* of this Association. During the last century, the science of Applied Mechanics has made strides which astonish us by their magnitude; but even these, it may reasonably be hoped, are but the promises of future and more wonderful enlargements. I, therefore, propose to offer a succinct history of these improvements, as an instance of the influence of scientific progress on the well-being of society. I shall take in review the three chief aids which engineering science has afforded to national progress, namely, canals, steam navigation and railways; each of which has promoted an incalculable extension of the industrial resources of the country. One hundred years ago, the only means for the conveyance of inland merchandise, were the packhorses and waggons on the then imperfect

highways. It was reserved for Brindley, Smeaton and others to introduce a system of canals, which opened up facilities for an interchange of commodities at a cheap rate over almost every part of the country. The impetus given to industrial operations by this new system of conveyance induced capitalists to embark in trade, in mining, and in the extension of manufactures in almost every district. These improvements continued for a series of years, until the whole country was intersected by canals, requisite to meet the demands of a greatly extended industry. But canals, however well adapted for the transport of minerals and merchandise, were less suited for the conveyance of passengers. The speed of the canal boats seldom exceeded from 2½ to 3 miles an hour; and, in addition to this, the projectors of canals sometimes sought to take an unfair advantage of the Act of Parliament, which fixed the tariff at so much per ton per mile, by adopting circuitous routes, under the erroneous impression that mileage was a consideration of great importance in the success of such undertakings. It is in consequence of short-sighted views and imperfect legislation that we inherit the numerous curves and distortions of our canal system. These defects in construction rendered canals almost useless for the conveyance of passengers, and led to the improvement of the common roads and the system of stage coaches so that before the year 1830 the chief public highways of the country had attained a remarkable smoothness and perfection; and the lightness of our carriages, and the celerity with which they were driven, still excite the admiration of those who remember them. These days of an efficiently worked system, which tasked the power and speed of the horse to the utmost, have now been succeeded by changes more wonderful than any that previously occurred in the history of the human race.

Scarcely had the canal system been fully developed when a new means of propulsion was adopted—namely, steam. I need not recount to you the enterprise, skill, and labour that have been exerted in connexion with steam navigation. You have seen its results on every river and every sea; results we owe to the fruitful minds of Miller, Symington, Fulton, and Henry Bell, who were the pioneers in the great march of progress. Viewing the past, with a knowledge of the present and a prospect of the future, it is difficult to estimate sufficiently the benefits that have been conferred by this application of mechanical science to the purposes of navigation. Power, speed, and certainty of action have been attained on the most gigantic scale. The celerity with which a modern steamer, with a thousand tons of merchandise and some hundreds of human beings on board, cleaves the water and pursues her course, far surpasses the most sanguine expectations of a quarter of a century ago, and indeed almost rivals the speed of the locomotive itself. Previous to 1812 our intercourse with foreign countries and with our colonial possessions depended entirely upon the state of the weather. It was only in favourable seasons that a passage was open, and we had often to wait days, or even a week, before Dublin could be reached from Holyhead. Now this distance of sixty-three miles is accomplished in all weathers in little more than three hours. The passage to America used to occupy six weeks or two months; now it is accomplished in eight or nine days. The passage round the Cape to India is reduced from nearly half a year to less than a third of that time, while that country may be reached by the overland route in less than a month.

These are a few of the benefits derived from steam navigation, and, as it is yet far from perfect, we may reasonably calculate on still greater advantages in our intercourse with distant nations. I will not here enter on the subject of the numerous improvements which have so rapidly advanced the progress of this important service. Suffice it to observe that the paddle-wheel system of propulsion has maintained its superiority over every other method yet adopted for the attainment of speed, as by it the best results are obtained with the least expenditure of power. In ships of war the screw is indispensable, on account of the security it affords to the engines and machinery, from their position in the hold below the water-line, and because of the facility it offers in the use of sails, when the screw is raised from its position in the well to a recess in the stern prepared for that purpose. It is also preferable in ships which require auxiliary power in calms and adverse winds, so as to expedite the voyage and effect a considerable saving upon the freight.

The public mind had scarcely recovered itself from the changes which steam navigation had caused, and the impulse

it had given to commerce, when a new and even more gigantic power of locomotion was inaugurated. Less than a quarter of a century had elapsed since the first steamboats floated on the waters of the Hudson and the Clyde, when the achievements thence resulting were followed by the application of the same agency to the almost superhuman flight of the locomotive and its attendant train. I well remember the competition at Rainhill in 1825, and the incredulity everywhere evinced at the proposal to run locomotives at twenty miles an hour. Neither George Stephenson himself, nor anyone else, had at that time the most distant idea of the capabilities of the railway system. On the contrary, it was generally considered impossible to exceed ten or twelve miles an hour; and our present high velocities, due to high-pressure steam and the tubular system of boilers, have surpassed the most sanguine expectations of engineers. The sagacity of George Stephenson at once seized upon the suggestions of Henry Booth, to employ tubular boilers; and that, united to the blast-pipe, previously known, has been the means of effecting all the wonders we now witness in a system that has done more for the development of practical science, and the civilization of man, than any discovery since the days of Adam.

From a consideration of the changes which have been effected in the means for the interchange of commodities, I pass on to examine the progress which has been made in their production. And, as the steam-engine has been the basis of all our modern manufacturing industry, I shall glance at the steps by which it has been perfected. Passing over the somewhat mythical fame of the Marquis of Worcester and the labours of Savery, Beighton, and Newcomen, we come at once to discuss the state of mechanical art at the time when James Watt brought his gigantic powers to the improvement of the steam-engine. At that time the tools were of the rudest construction, nearly everything being done by hand, and, in consequence, wood was much more extensively employed than iron. Under these circumstances Watt invented separate condensation, rendered the engine double-acting, and converted its rectilinear motion into a circular one, suitable for the purposes of manufacture. But the discovery at first made little way, the public did not understand it, and a series of years elapsed before the difficulties, commercial and mechanical, which opposed its application, could be overcome. When the certainty of success had been demonstrated, Watt was harassed by infringements of his patent, and lawsuits for the maintenance of his rights. Inventors, and pretended inventors, set up claims, and entered into combination with manufacturers, miners, and others, to destroy the patent and deprive him of the just fruits of his labour and genius. Such is the selfish heartlessness of mankind in dealing with discoveries not their own, but from which they expect to derive benefit. The steam-engine, since it was introduced by Watt, has changed our habits in almost every condition of life. Things which were luxuries have become necessities, and it has given to the poor man in all countries in which it exists a degree of comfort and independence and a participation in intellectual culture unknown before its introduction. It has increased our manufactures tenfold, and has lessened the barriers which time and space interpose. It ploughs the land and winnows and grinds the corn. It spins and weaves our textile fabrics. In mining it pumps, winds, and crushes the ore. It performs these things with powers so great and so energetic as to astonish us at their immensity, while they are at the same time perfectly docile, and completely under human control. In war it furnishes the means of aggression, as in peace it affords the bonds of conciliation, and, in fact, places within reach a power which, properly applied, produces harmony and good will among men, and leads to the happiest results in every condition of human existence. We may, therefore, well be proud of the honour conferred on this country as the cradle of its origin, and as having fostered its development from its earliest applications to its present high state of perfection. I cannot conclude this notice of the steam-engine without observing the changes it is destined to effect in the cultivation of the soil. It is but a short time since it was thought inapplicable to agricultural purposes from its great weight and expense. But more recent experience has proved this to be a mistake, and already in most districts we find that it has been pressed into the service of the farm. The small locomotive, mounted on a frame with four wheels, travels from village to village with its attendant, the thrashing machine,

performing the operations of thrashing, winnowing, and cleansing, at less than one-half the cost by the old and tedious process of hand-labour. Its application to ploughing and tillage on a large scale is, in my opinion, still in its infancy, and I doubt not that many members of this Association will live to see the steam-plough in operation over the whole length and breadth of the land. Much has to be done before this important change can be successfully accomplished; but, with the aid of the agriculturist preparing the land so as to meet the requirements of steam machinery, we may reasonably look forward to a new era in the cultivation of the soil. The extraordinary developments of practical science in our system of textile manufacture are, however, not entirely due to the steam-engine, although they are now in a great measure dependent on it. The machinery of these manufactures had its origin before the steam-engine had been applied, except for mining purposes; and the inventions of Arkwright, Hargreaves, and Crompton were not conceived under the impression that steam would be their moving power. On the contrary, they depended upon water; and the cotton machinery of this district had attained considerable perfection before steam came to the aid of the manufacturer, and ultimately enabled him to increase the production to its present enormous extent.

I shall not attempt a description of the machinery of the textile manufactures, because ocular inspection will be far more acceptable. I can only refer you to a list of establishments in which you may examine their operations on a large scale, and which I earnestly recommend to your attention. I may, however, advert to a few of the improvements which have marked the progress of the manufacturing system in this country. When Arkwright patented his water-frames in 1767, the annual consumption of cotton was about 4,000,000lb. weight. Now it is 1,200,000,000lb. weight—300 times as much. Within half a century the number of spindles at work, spinning cotton alone, has increased ten-fold; while, by superior mechanism, each spindle produces fifty per cent. more yarn than on the old system. Hence the importance to which the cotton trade has risen, equalling at the present time the whole revenue of the three kingdoms, or 70,000,000*l.* sterling per annum. As late as 1820 the power-loom was not in existence; now it produces about 14,000,000 yards of cloth, or, in more familiar terms, nearly 8000 miles of cloth per diem. I give these particulars to show the immense power of production of this country, and to afford some conception of the number and quality of the machines which effect such wonderful results. Mule spinning was introduced by Crompton, in 1787, with about twenty spindles to each machine. The powers of the machine were, however, rapidly increased; and now it has been so perfected that 2000 or even 3000 spindles are directed by a single person. At first the winding on, or forming the shape of the cop, was performed by hand; but this has been superseded by rendering the machine automatic, so that it now performs the whole operation of drawing, stretching, and twisting the thread, and winding it on to the exact form, ready for the reel or shuttle as may be required. These and other improvements in carding, roving, combing, spinning, and weaving, have established in this country an entirely new system of industry; it has given employment to greatly increased numbers, and a more intelligent class of work-people. Similarly important improvements have been applied to the machinery employed in the manufacture of silk, flax, and wool; and we have only to watch the processes in these different departments to be convinced that they owe much to the development of the cotton manufacture. In the manufacture of worsted, the spinning-jenny was not employed at Bradford until 1790, nor the power-loom until about 1825. The production of fancy or mixed goods from alpaca and mohair wool, introduced to this country in 1836, is, perhaps, the most striking example of a new creation in the art of manufacture, and is chiefly due to Mr. Titus Salt, in whose immense palace of industry, at Saltaire, it may be seen in the greatest perfection. In flax machinery, the late Sir Peter Fairbairn was one of the most successful inventors, and his improvements have contributed to the rapid extension of this manufacture.

I might greatly extend this description of our manufacturing industry, but I must for the present be brief, in order to point out the dependence of all these improvements on the iron and coal so widely distributed among the mineral treasures of our island. We are highly favoured in the abundance of these minerals, deposited with an un-

sparing hand by the great Author of Nature, under so slight a covering as to bring them within reach of the miner's art. To them we owe our present high state of perfection in the useful arts; and to their extended application we may safely attribute our national progress and wealth. So that, looking to the many blessings which we daily and hourly receive from these sources alone, we are impressed with devotional feelings of gratitude to the Almighty for the manifold bounties He has bestowed on us. Previously to the inventions of Henry Cort, the manufacture of wrought iron was of the most crude and primitive description. A hearth and a pair of bellows was all that was employed. But since the introduction of puddling, the iron-masters have increased the production to an extraordinary extent, down to the present time, when processes for the direct conversion of wrought iron on a large scale are being attempted. A consecutive series of chemical researches into the different processes, from the calcining of the ore to the production of the bar, carried on by Dr. Percy and others, has led to a revolution in the manufacture of iron; and although it is at the present moment in a state of transition, it nevertheless requires no very great discernment to perceive that steel and iron of any required tenacity will be made in the same furnace, with a facility and certainty never before attained. This has been effected to some extent by improvements in puddling; but the process of Mr. Bessemer—first made known at the meeting of this Association at Cheltenham—affords the highest promise of certainty and perfection in the operation of converting the melted pig direct into steel or iron, and as likely to lead to the most important developments in this manufacture. These improvements in the production of the material must, in their turn, stimulate its application on a large scale and lead to new constructions.

In iron shipbuilding an immense field is opening before us. Our wooden walls have to all appearance seen their last days; and as one of the early pioneers in iron construction, as applied to shipbuilding, I am highly gratified to witness a change of opinion that augurs well for the security of the liberties of the country. From the commencement of iron shipbuilding in 1830 to the present time, there could only be one opinion among those best acquainted with the subject, namely, that iron must eventually supersede timber in every form of naval construction. The large ocean steamers, the *Himalaya*, the *Persia*, and the *Great Eastern*, abundantly show what can be done with iron, and we have only to look at the new system of casing ships with armour plates, to be convinced that we can no longer build wooden vessels of war with safety to our naval superiority and the best interests of the country. I give no opinion as to the details of the reconstruction of the Navy—that is reserved for another place—but I may state that I am fully persuaded that the whole of our ships of war must be rebuilt of iron, and defended with iron armour calculated to resist projectiles of the heaviest description at high velocities. In the earlier stages of iron shipbuilding, I believe I was the first to show, by a long series of experiments, the superiority of wrought iron over every other description of material in security and strength, when judiciously applied in the construction of ships of every class. Other considerations, however, affect the question of vessels of war; and although numerous experiments were made, yet none of the targets were on a scale sufficient to resist more than a six-pounder shot. It was reserved for our scientific neighbours, the French, to introduce thick iron plates as a defensive armour for ships. The success which has attended the adoption of this new system of defence affords the prospect of invulnerable ships of war, and hence the desire of the Government to remodel the Navy on an entirely new principle of construction, in order that we may retain its superiority as the great bulwark of the nation. A committee has been appointed by the War-office and the Admiralty for the purpose of carrying out a scientific investigation of the subject, so as to determine, first, the best description of material to resist projectiles; secondly, the best method of fastening and applying that material to the sides of ships and land fortifications; and, lastly, the thickness necessary to resist the different descriptions of ordnance.

It is asserted, probably with truth, that whatever thickness of plates is adopted for casing ships, guns will be constructed capable of destroying them. But their destruction will even then be a work of time, and I believe, from what I have seen in recent experiments, that with proper armour it would require, not only the most powerful ordnance, but also a great

concentration of fire, before fracture will ensue. If this be the case, a well-constructed iron ship, covered with sound plates of the proper thickness, firmly attached to its sides, will, for a considerable time, resist the heaviest guns which can be brought to bear against it, and be practically shot-proof. But our present means are inadequate for the production of large masses of iron, and we may trust that, with new tools and machinery, and the skill, energy, and perseverance of our manufacturers, every difficulty will be overcome, and armour plates produced which will resist the heaviest existing ordnance. The rifling of heavy ordnance, the introduction of wrought iron, and the new principle of construction with strained hoops, have given to all countries the means of increasing enormously the destructive power of their ordnance. One of the results of this introduction of wrought iron and correct principles of manufacture, is the reduction of the weight of the new guns to about two-thirds the weight of the older cast-iron ordnance. Hence follows the facility with which guns of much greater power can be worked, while the range and precision of fire are at the same time increased. But these improvements cannot be confined to ourselves. Other nations are increasing the power and range of their artillery in a similar degree, and the energies of the nation must, therefore, be directed to maintain the superiority of our Navy in armour as well as in armament.

We have already seen a new era in the history of the construction of bridges, resulting from the use of iron; and we have only to examine those of the tubular form over the Conway and Menai Straits to be convinced of the durability, strength, and lightness of tubular constructions applied to the support of railways or common roads in spans which ten years ago were considered beyond the reach of human skill. When it is considered that stone bridges do not exceed 150 feet in span, nor cast-iron bridges 250 feet, we can estimate the progress which has been made in crossing rivers 400 or 500 feet in width, without any support at the middle of the stream. Even spans greatly in excess of this may be bridged over with safety, provided we do not exceed 1800 to 2000 feet, when the structure would be destroyed by its own weight.

It is to the exactitude and accuracy of our machine tools that our machinery of the present time owes its smoothness of motion and certainty of action. When I first entered this city the whole of the machinery was executed by hand. There were neither planing, slotting, nor shaping-machines, and, with the exception of very imperfect lathes and a few drills, the preparatory operations of construction were effected entirely by the hands of the workmen. Now everything is done by machine tools with a degree of accuracy which the unaided hand could never accomplish. The automaton, or self-acting machine tool, has within itself an almost creative power; in fact, so great are its powers of adaptation, that there is no operation of the human hand that it does not imitate. For many of these improvements the country is indebted to the genius of our townsmen, Mr. Richard Roberts and Mr. Joseph Whitworth. The importance of these constructive machines is, moreover, strikingly exemplified in the Government Works at Woolwich and at Enfield, chiefly arranged under the direction of Mr. Anderson, the present inspector of machinery, to whose skill and ingenuity the country is greatly indebted for the efficient state of those great arsenals.

Among the changes which have largely contributed to the comfort and enjoyment of life, are the improvements in the sanitary condition of towns. These belong probably to the province of social rather than mechanical science; but I cannot omit to notice some of the great works that have of late years been constructed for the supply of water and for the drainage of towns. In former days 10 gallons of water to each person per day was considered an ample allowance. Now, 30 gallons is much nearer the rate of consumption. I may instance the water-works of this city and of Liverpool, each of which yield a supply of from 20 to 30 gallons of water to each inhabitant. In the former case the water is collected from the Cheshire and Derbyshire hills, and, after being conveyed in tunnels and aqueducts a distance of 10 miles to a reservoir, where it is strained and purified, it is ultimately taken a further distance of 8 miles in pipes, in a perfectly pure state, ready for distribution. The greatest undertaking of this kind, however, yet accomplished is that by which the pure waters of Loch Katrine are distributed to the city of Glasgow. This work, recently completed by Mr. Bateman, who was also the constructor of the waterworks of this city, is of the most gigantic character, the water being

conveyed in a covered tunnel a distance of 27 miles through an almost impassable country to the service reservoir, about 8 miles from Glasgow. By this means 40 million gallons of water per day are conveyed through the hills which flank Ben Lomond, and after traversing the sides of Loch Chon and Loch Aird, are finally discharged into the Mudgock Basin, where the water is impounded for distribution. We may reasonably look forward to an extension of similar benefits to the metropolis, by the same engineer, whose energies are now directed to an examination of the pure fountains of Wales, from whence the future supply of water to the great city is likely to be derived. A work of so gigantic a character may be looked upon as problematical, but when it is known that six or seven millions of money would be sufficient for its execution, I can see no reason why an undertaking of so much consequence to the health of London should not ultimately be accomplished.

In leaving this subject, I cannot refrain from an expression of deep regret at the loss which science has sustained through the death of one of our Vice-Presidents, the late Professor Hodgkinson. For a long series of years he and I worked together in the same field of scientific research, and our labours are recorded in the *Transactions* of this and other Associations. To Mr. Hodgkinson we owe the determination of the true form of cast iron beams, or section of greatest strength; the law of the elasticity of iron under tensile and compressive forces; and the laws of resistance of columns to compression. I look back to the days of our joint labour with unalloyed pleasure and satisfaction.

I regret to say that another of our Vice-Presidents, my friend, Mr. Joseph Whitworth, is unable to be present with us through serious, but I hope not dangerous, illness. To Mr. Whitworth mechanical science is indebted for some of the most accurate and delicate pieces of mechanism ever executed; and the exactitude he has introduced into every mechanical operation will long continue to be the admiration of posterity. His system of screw threads and gauges is now in general use throughout Europe. We owe to him a machine for measuring with accuracy to the millionth of an inch, employed in the production of standard gauges; and his laborious and interesting experiments on rifled ordnance have resulted in the production of a rifled small arm and gun which have never been surpassed for range and precision of fire. It is with pain that I have to refer to the cause which deprives me of his presence and support at this meeting.

A brief allusion must be made to that marvellous discovery which has given to the present generation the power to turn the spark of heaven to the uses of speech, to transmit along the slender wire for a thousand miles a current of electricity that renders intelligible words and thoughts. This wonderful discovery, so familiar to us, and so useful in our communications to every part of the globe, we owe to Wheatstone, Thomson, De la Rive, and others. In land telegraphy the chief difficulties have been surmounted, but in submarine telegraphy much remains to be accomplished. Failures have been repeated so often as to call for a Commission on the part of the Government to inquire into the causes, and the best means of overcoming the difficulties which present themselves. I had the honour to serve on that Commission, and I believe that from the report, and mass of evidence and experimental research accumulated, the public will derive very important information. It is well known that three conditions are essential to success in the construction of ocean telegraphs—perfect insulation, external protection, and appropriate apparatus for laying the cable safely on its ocean bed. That we are far from having succeeded in fulfilling these conditions is evident from the fact that out of 12,000 miles of submarine cable which have been laid since 1851, only 3000 miles are actually in working order; so that three-fourths may be considered as a failure and loss to the country. The insulators hitherto employed are subject to deterioration from mechanical violence, from chemical decomposition or decay, and from the absorption of water; but the last circumstance does not appear to influence seriously the durability of cables. Electrically, india-rubber possesses high advantages, and, next to it, Wray's compound and pure gutta percha far surpass the commercial gutta percha hitherto employed; but it remains to be seen whether the mechanical and commercial difficulties in the employment of these new materials can be successfully overcome. The external protecting covering is still a subject of anxious consideration. The objections to iron wire are its weight and liability to corrosion. Hemp has been sub-

stituted, but at present with no satisfactory result. All these difficulties, together with those connected with the coiling and paying out of the cable, will no doubt yield to careful experiment and the employment of proper instruments in its construction, and its final deposit on the bed of the ocean. Irrespective of inland and international telegraphy, a new system of communication has been introduced by Professor Wheatstone, whereby intercourse can be carried on between private families, public offices, and the works of merchants and manufacturers. This application of electric currents cannot be too highly appreciated, from its great efficiency and comparatively small expense. To show to what an extent this improvement has been carried, I may state that 1000 wires in a perfect state of insulation, may be formed into a rope not exceeding half-an-inch in diameter.

I must not sit down without directing attention to a subject of deep importance to all classes,—namely, the amount of protection inventors should receive from the laws of the country. It is the opinion of many that patent laws are injurious rather than beneficial, and that no legal protection of this kind ought to be granted: in fact, that a free trade in inventions, as in everything else should be established. I confess I am not of that opinion. Doubtless there are abuses in the working of the patent law as it at present exists, and protection is often granted to pirates and impostors, to the detriment of real inventors. This, however, does not contravene the principle of protection, but rather calls for reform and amendment. It is asserted by those who have done the least to benefit their country by inventions, that a monopoly is injurious, and that if the patent laws are defended, it should be, not on the ground of their benefit to the inventor, but on that of their utility to the nation. I believe this to be a dangerous doctrine, and I hope it will never be acted upon. I cannot see the right of the nation to appropriate the labours of a lifetime, without awarding any remuneration. The nation, in this case, receives a benefit; and assuredly the labourer is worthy of his hire. I am no friend of monopoly, but neither am I a friend of injustice; and I think that before the public are benefited by an invention, the inventor should be rewarded either by a fourteen years' monopoly, or in some other way. Our patent laws are defective, so far as they protect pretended inventions; but they are essential to the best interests of the State in stimulating the exertions of a class of eminent men, such as Arkwright, Watt, and Crompton, whose inventions have entailed upon all countries invaluable benefits, and have done honour to the human race. To this Association is committed the task of correcting the abuses of the present system, and establishing such legal provisions as shall deal out equal justice to the inventor and the nation at large.

I must not forget that we owe very much to an entirely new and most attractive method of diffusing knowledge, admirably exemplified in the Great Exhibition of 1851, and its successors in France, Ireland and America. Most of us remember the gems of Art which were accumulated in this city during the summer of 1857, and the wonderful results they produced on all classes of the community. The improvement of taste, and the increase of practical knowledge which followed these Exhibitions have been deeply felt; and hence the prospects which are now opening before us in regard to the Exhibition of the next year cannot be too highly appreciated. That Exhibition will embrace the whole circle of the sciences, and is likely to elevate the general culture of the public to a higher standard than we have ever before attained. There will be unfolded almost every known production of art, every ingenious contrivance in machinery, and the results of discoveries in science from the earliest period. The fine arts, which constituted no part of the Exhibition of 1851, and which were only partially represented at Paris and Dublin, will be illustrated by new creations from the most distinguished masters of the modern school. Looking forwards, I venture to hope for a great success and a further development of the principle advocated by this Association—the union of Science and Art.

In conclusion, my apologies are due to you for the length of this address, and I thank you sincerely for the patient attention with which you have listened to the remarks I have had the honour to lay before you. As the President of the British Association, I feel that far beyond the consideration of merely personal qualifications, my election was intended as a compliment to practical science, and to this great and influential metropolis of manufacture; where those

who cultivate the theory of science may witness, on its grandest scale, its application to the industrial arts. As a citizen of Manchester, I venture to assure the Association that its intentions are appreciated; and to its members, as well as to the strangers who have been attracted here by this meeting, I offer a most cordial welcome.

On Thursday, the 5th inst., the Sectional Meetings commenced. The Sections are the following:—

A.—Mathematical and Physical Science.—*President*: G. B. Airey, Esq., D.C.L., F.R.S., Astronomer Royal.
B.—Chemical Science.—*President*: W. A. Miller, M.D., F.R.S., Professor of Chemistry, King's College, London.

C.—Geology.—*President*: Sir R. I. Murchison, G.C.St.S., D.C.L., F.R.S., Director-General of the Geological Survey of the United Kingdom.

D.—Zoology and Botany.—*President*: C. C. Babington, Esq., M.A., F.R.S., Professor of Botany, Cambridge.

E.—Sub-Section Physiology.

F.—Economic Science.—*President*: John Craufurd, Esq., F.R.S., President of the Ethnological Society.

G.—Mechanical Science.—*President*: John F. Bateman, Esq., C.E., F.R.S.

NOTICES OF BOOKS.

A Guide to Croft Spa. By Miss D. WILKINSON. Darlington: Times' Office. 1861.

At this season of the year the very word Spa has a refreshing look and sound to the overtaken inhabitant of a crowded city. It speaks of shady walks by bubbling streams, through leafy woods just tinged and crisped by autumn winds; and rest and solace for a jaded mind, with fresh health and vigour for a hard-worked frame. But, as chemists and reviewers, we must avoid sentiment, and proceed to business.

Croft deserves to be better known. It may be placed at the head of the list of English *Thiopege*s; and, indeed, in respect of the amount of sulphuretted hydrogen contained in the water of one spring, it may rank before all the Continental spas except Schwyznach in Switzerland.

The village lies in a sheltered valley on the south bank of the Tees at the very edge of Yorkshire. On a gravelly soil, in the midst of a rich, luxuriant, well-cultivated country, and defended on all sides from inclement breezes, the air is dry, and pure, and mild, while the scenery around the village, if wanting in the grander aspects of Nature, presents that charming combination of hill and dale with winding stream, wood, pasture-land, and corn-field, which makes up the "quiet, delicate beauty" of an English landscape.

But the mineral springs are, of course, the principal attraction at Croft. There are four of them, three containing sulphuretted hydrogen, and another, from the absence of this gas, denominated the Sweet Well. The water of the New Spa contains a larger quantity of sulphuretted hydrogen than any other medicinal spring in England. According to the analysis of Dr. Cossar, quoted by Miss Wilkinson, it amounts to 20.56 cubic inches in the gallon; but Mr. Walker's analysis gives as much as 22.2 cubic inches. This is considerably more than is found in Harrogate water, or in that of Weilbach, the most frequented sulphur spring on the Continent. For the various hepatic, cutaneous, and other disorders for which sulphurous waters are recommended, the Croft Springs are therefore to be preferred.

With regard to the other matters, however, our authorities differ considerably; and we place the analyses of the New Spa, by Dr. Cossar and Mr. Walker, in juxtaposition with the hint that any person interested in the prosperity of Croft had better employ a competent chemist to make an exact determination of the ingredients.

position with the hint that any person interested in the prosperity of Croft had better employ a competent chemist to make an exact determination of the ingredients.

	Cossar.	Walker.
Water of New Spa. In one gallon.	Cubic inches.	Cubic inches.
Sulphuretted hydrogen	20.56	22.2
Carbonic acid	40.216	15.2
Nitrogen and carburetted hydrogen	..	4.8
Gaseous contents	60.776	42.2
	Grains.	Grains.
Carbonate of lime	23.60	64.0
Carbonate of magnesia	4.56	..
Sulphate of lime	141.68	8.0
Sulphate of magnesia	13.72	67.2
Sulphate of soda	18.82	..
Chloride of sodium	5.92	..
Chloride of calcium	..	19.2
Saline matter	208.30	158.4

Miss Wilkinson only gives Dr. Cossar's analysis, but without Mr. Walker's we should have been greatly puzzled by one sentence in her little work. She writes:—"The sulphur water is often drunk warm with a spoonful of common salt in it, which tends to strengthen the stomach, enabling it to bear the otherwise raw potency of the chloride of calcium." None of this latter salt appears in the analyses our authoress quotes, and only a very small amount of chloride of sodium, so one or the other of the chemists we have named must have made some mistake in the estimation of the chlorine. The other differences are remarkable, and, as we have said, it would be well to have them settled.

There is nothing more to notice in the chemical, and the archaeological and topographical information which Miss Wilkinson gives does not concern us here. We may assure our readers, however, that they will find a good account of all that is interesting in and around the neighbourhood. There is a good hotel at Croft, a respectable inn, and plenty of private lodgings, the last having "a character of aristocratic rural comfort rarely found in the more crowded watering-places." Altogether it seems to be a very desirable residence for invalids. We advise all who are recommended to a sulphur spring to consult Miss Wilkinson's little book; and let those who have no wish to mix with the fashion and gaieties of Harrogate, who have no knowledge of French or German, whose appetites fail before foreign cookery, or whose spirits rebel against Continental police regulations, go down to Croft, and there get all the benefit to be derived from drinking or bathing in sulphur-water, with pure air and healthful exercise in quiet scenery; and then let them thank Miss Wilkinson for having brought the knowledge of the place home to them.

CORRESPONDENCE.

White Gunpowder.

To the Editor of the CHEMICAL NEWS.

SIR,—In reply to the letter of "J. M. C." in your Journal of August 31, respecting the grinding of white gunpowder prepared by the moist process, I beg to state that the plan now adopted is that of crushing the dry mass between wooden rollers, and then sieving; by this means it is reduced to the condition of a powder, the fineness of which will depend upon the number of meshes to the square inch of the sieve employed. I do not find that the powder has a tendency to cake, or form hard lumps when exposed to the air. I have now some samples by me, prepared upwards of a month ago, that

have been exposed to air, which have not caked to any appreciable extent.

I send a small sample of white gunpowder prepared in this way; the proportions chlorate of potash 49 parts, yellow prussiate of potash 28 parts, and cane sugar 23 parts, are those given by Dr. Pohl in your Journal. If "J. M. C." will try the experiments of grinding a portion with a tolerable amount of pressure in a stone or Wedgewood mortar, he will have no longer any doubts respecting the possibility or impossibility of its exploding (or igniting) by trituration between stones, or when struck a smart blow with a hammer, upon a stone.

I shall be happy to forward "J. M. C." a sample of white gunpowder prepared by the above-mentioned process if he will send me his address.—I am, &c.

F. HUDSON.

Laboratory, 68, Corporation Street, Manchester.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Specific Gravity of Ammonia.—Jolly has made some experiments (*Annal. der Chem. und Pharm.* Bd. cxvii. s. 181), and obtained numbers which differ slightly from the determinations of others. The specific gravity of pure liquid ammonia at 0° and in relation to water at the same temperature he found to equal

I.	II.	III.
0.6239	0.6261	0.6193.

The specific gravity of gaseous ammonia relatively to that of atmospheric air at 0° and pressure 715 mm., he found to equal

I.	II.	III.
0.558	0.576	0.565

The above numbers differ a little from those given by Faraday, Biot, and Arago.

II. ANALYTICAL CHEMISTRY.

Influence of Free Ammonia and Ammoniacal Salts on the Precipitation of Nickel, Cobalt, Zinc, Manganese, Iron, and Uranium, by Sulphide of Ammonium.—Fresenius publishes (*Journ. für Prakt. Chem.* Bd. lxxxii. s. 257) the result of a long investigation undertaken to test the truth of Terrell's assertion that the presence of ammonia and ammoniacal salts hindered the complete precipitation of manganese, cobalt, nickel, and zinc by sulphide of ammonium. The author gives copious details of his experiments which sometimes confirm, but generally contradict, Terrell. We select and condense some of the results:—

Nickel.—Colourless or yellow sulphide of ammonium precipitates very slowly a salt of nickel oxide, and traces of nickel remain in solution. Sal ammoniac greatly assists the precipitation after some time. Free ammonia is most prejudicial. The precipitation is most complete with sal ammoniac and a slight excess of sulphide of ammonium.

Cobalt.—Very dilute solutions of salts of cobaltous oxide are not precipitated by sulphide of ammonium alone, even on long standing. Sal ammoniac assists the complete precipitation after a time. Ammonia hinders the complete precipitation, but only in a slight degree. Whether colourless or yellow sulphide is used, the results are the same. Under the most favourable conditions the sulphide will precipitate a solution of cobalt containing only $\frac{1}{100000}$ th part.

Zinc.—Colourless sulphide of ammonium will precipitate slowly a pure neutral zinc solution. Sal ammoniac assists the complete precipitation. Free ammonia causes the precipitate to remain suspended a longer time, but beyond this has no injurious influence. With sal ammoniac the yellow sulphide answers as well as the colourless. Zinc may be precipitated from a solution containing only $\frac{1}{100000}$ th part.

Manganese.—Pure sulphide of ammonium will not pre-

cipitate a very dilute manganese solution. Sal ammoniac favours the precipitation after some time. Ammonia in the presence of sal ammoniac does not appear either to assist or hinder the precipitation. Yellow and colourless sulphide appear to act very much alike; but the latter is, perhaps, to be preferred. The reagent is not so sensitive with manganese as with zinc, nickel, and cobalt, but a solution containing from $\frac{1}{100000}$ to $\frac{1}{1000000}$ th part is soon precipitated and in the course of time as little as $\frac{1}{1000000}$ th. When a manganeous oxide solution was precipitated by the sulphide in the presence of sal ammoniac, the author observed that the flesh-coloured precipitate changed after some days to a green, an appearance which had never before been remarked. This change of colour is obviously caused by the passage of the hydrated sulphide of manganese into the anhydrous. The change of colour begins at one spot and gradually spreads over the whole precipitate.

Iron.—Ferrous Oxide.—Pure sulphide of ammonium, colourless or yellow, precipitates a solution of ferrous oxide slowly but completely. Sal ammoniac greatly assists the precipitation after a time. Free ammonia is not appreciably detrimental. Colourless or clear yellow sulphide has the same effect.

Ferric Oxide.—Pure sulphide of ammonium, colourless or yellow, precipitates a dilute solution of ferric oxide slowly and imperfectly, or not at all. Sal ammoniac assists the precipitation. Free ammonia is no disadvantage: a small quantity may be of some advantage in hastening the precipitation. Colourless or yellow sulphide answers equally well.

Uranium.—The precipitation of uranic oxide from very dilute solutions requires a long time. Colourless sulphide appears to act somewhat quicker than yellow. Sal ammoniac promotes the precipitation after some time, and free ammonia may assist. The colour of the precipitates depends on the presence and amount of sal ammoniac, ammonia, and sulphide of ammonium.

III. ORGANIC CHEMISTRY.

The Fixation of Ammonia.—M. Schützenberger (*Bulletin de la Société Chimique de Paris*, i., p. 16) has also made experiments similar to those of M. Thenard, with analogous results. He extended his investigations to the vegetable colouring matters, and found that when these were heated with ammonia in a sealed tube, that they also fixed the gas which was not removed by the strong acids nor disengaged by hydrate of lime.

Luteoline.—The colouring matter of the woad according to Schützenberger and Paraf (*Ibid.* ii., p. 18), is easily obtained pure by extracting in a displacement apparatus with boiling alcohol. The concentrated alcoholic solution is then precipitated by water, the precipitate dried, and the luteoline separated from the resinous matter by sublimation, in which way it is obtained in beautiful golden yellow acicular crystals. The analysis of the crystals led to the formula $C_{24}H_8O_{10}$. Luteoline dissolves when heated in a sealed tube with caustic ammonia, and the solution evaporated to dryness, leaves a residue which evolves ammonia when treated with caustic potash.

MISCELLANEOUS.

THE WATER BAROMETER AT THE CRYSTAL PALACE.

THE scientific visitor to the Crystal Palace will find a new object of interest in the Water Barometer which has recently been erected within the building at Sydenham. The instrument is remarkable not merely by reason of its unique character in point of construction, but bespeaks an additional claim to our notice from the circumstance of its having been originally fitted up, by Professor Daniell, against the staircase wall of the apartments occupied until

lately by the Royal Society at Somerset House, and where for nearly thirty years it has registered in a very conspicuous manner the variations of barometric pressure.

The Council of the Royal Society having placed the instrument at the disposal of Mr. Glaisher, of Greenwich Observatory, that gentleman in turn negotiated its transfer to the Directors of the Crystal Palace, who at once took steps to provide at Sydenham a convenient place for its reception and exhibition, and within the last few days the reconstruction of the instrument has been successfully accomplished by Messrs. Negretti and Zambra, of Hatton Garden. The preliminary operation of removing the barometer from Somerset House was, after much difficulty, effected by them some months since, all arriving in safety at the Palace, with the exception of the breakage of about eighteen inches from the lower end of the barometer tube. Originally the tube was filled by means of a copper steam boiler, set in brickwork over a fire-place immediately under the barometer itself, so that the tube could be lowered into the boiler which has since formed its cistern.

The original plan of erection did not appear to be that most readily available for reconstructing the instrument at the Palace; firstly, because there was doubt as to the boiler being sufficiently strong to bear the necessary pressure, so that the water might be boiled almost throughout the tube and maintained for some time in a state of ebullition, and, secondly, on account of the existing regulations at the Crystal Palace not permitting fire to be lighted within the building. Under these circumstances it was suggested by Mr. Negretti to use an auxiliary boiler outside the building, and his object was first to boil the water in the cistern, allowing the steam to escape by a cock for some time, and then, by closing the cock, to drive steam through the tube until it escaped in a strong jet from its upper extremity, and then to boil the water in the tube till it issued from the top. By this means all the air would be expelled from the tube itself, and when this operation had continued long enough to temporarily seal the top while the water was still flowing out, and ultimately, by means of a judicious use of the blowpipe, to seal hermetically the top of the tube. Mr. Negretti was engaged for three days at the Palace preparing everything, and with great dexterity joined on a new piece of glass to the lower end of the barometer tube which had been broken, and another piece of glass likewise on to the upper extremity terminating in a small aperture.

The operation of filling and sealing the tube is thus described by Mr. Glaisher:—"On Thursday, August 29, everything was ready for the experiment, an auxiliary boiler was planted outside the building for generating steam, a pipe from which led to the boiler under the barometer itself into which distilled water in sufficient quantity had been placed, precautions having been taken to connect the pipe from the outer boiler with that in the inner boiler, with a portion of flexible tubing which would first yield if anything went wrong. After the connection was made, in about half an hour a current of steam issued from the cock. When this had continued for some time, the cock was closed, and the steam ascended into the tube, being at first condensed by the upper part of the tube, and ultimately rushing out at the top with considerable velocity. Water then ascended into the tube; and it was an anxious moment to watch the boiling water reach and pass where the tube had been joined, which, however, had been so admirably performed that all anxiety on this head soon ceased. After a time the upper extremity, while steam was rushing out, was closed, when the water ascended the tube and soon reached a point 32 feet from the surface of water in the boiler below. After this it was driven up, by steam, to very nearly the top of the continuation of the tube, but it did not reach quite up to the sealing point. A consultation now took place; it was almost resolved to let well alone, but it was ultimately determined to go through the same process again, as some

practical points had been suggested which promised to make the experiment yet more successful.

"The top of the tube was therefore opened, the water fell, and the operation repeated. It would be tedious to detail all the steps taken in the reboiling; the operation was eminently successful, and the tube was finally closed by the blow-pipe, and the column of water reached nearly 33 feet, without the slightest speck of air-bubble being perceptible.

"On Friday afternoon Mr. Negretti and I found the column of water 32 feet 9 inches in length, as measured from the surface in the cistern. This is equivalent to a column of 28.84 inches of mercury, considering the specific gravity of mercury as 13.624. The reading of a mercurial barometer at the same time was 29.86 inches; the difference between these two readings is 0.98 inch, and this difference should indicate the elastic force of aqueous vapour at the temperature at the time—viz., 78° if both instruments be correct. The elastic force of aqueous vapour at the temperature of 78° is 0.96 inch, differing by two hundredths of an inch only from that indicated by the water barometer, and completely satisfied me as to the accuracy of the operation, thus proving that the space above the water was free from air.

"I cannot close without expressing my sense of the ready resource of Mr. Negretti in overcoming every difficulty as it arose, and of the facility with which he performed and conducted every process connected with the operation."

The instrument is fixed in an angle of the Tropical Department, and near the great tree. The top of the column of water can be seen from the first gallery, and as that which causes a variation of an inch of mercury will cause a variation of more than a foot in the column of water, so the changes in the latter will be more than twelve times as great as in the former. Many oscillations, therefore, may be seen by the water which cannot be seen by the mercurial barometer, and in gales of wind or heavy storms it will be highly interesting to watch its action.

The principle of construction which renders this form of the barometer somewhat liable to get out of repair will not we trust materially falsify its indications for some time to come. The fact of water being a solvent for the gaseous components of the atmosphere must introduce a slight source of error, which will make itself apparent by a gradual diminution in the height of the water-column. The precautions taken against frost by the selection of the site appear fully sufficient to combat this formidable antagonist of the Water Barometer.

We may remark, in conclusion, that the Crystal Palace, from its offering such rare facilities in regard to height, appears peculiarly adapted for the exhibition of a gigantic Foucault's pendulum, which, like the philosophical instrument just now erected, would probably have an interest for the majority of the numerous visitors.

The City Gas Companies.—A joint circular has been issued by the City Gas Companies, notifying that, in consequence of the recent Act for Regulating the Supply of Gas to the Metropolis requiring, under heavy penalties, a greatly increased standard of illuminating power and purity, which will necessarily involve an increased cost of production, the Companies supplying the City of London will in future charge 4s. 6d. per 1000 ft. for the ordinary coal gas.

Phosphuretted Hydrogen.—Professor Graham has shown that phosphuretted hydrogen, although not spontaneously inflammable, becomes so when brought in contact with a small quantity of nitrous acid. M. Landolt has furnished an elegant mode of showing this fact. Some phosphuretted hydrogen, not spontaneously inflammable, prepared by heating some phosphorus with a concentrated solution of potash with double its volume

of alcohol, is directed towards a layer of nitric acid in a capsule. If the acid be about the density of 1.34, and if it is deprived of its hyponitric acid by boiling, the bubbles of phosphuretted hydrogen will traverse it without ignition. But if only a few drops of the fuming acid be added, each bubble of the gas will immediately inflame. Too much of the fuming acid will suspend the action, by decomposing the gas.

Oil Springs in America.—We have several times recently called attention to the oil springs of the United States and Canada. These springs have already become a new and increasing source of wealth. In Canada there are nearly 100 wells yielding oil. The land which contains the springs is leased in patches of acres or half acres. The lessors generally give 300 dollars for the privilege and one third of the oil drawn from the wells. A correspondent says: "The wells are sunk and cribbed to a depth of from 40 to 60 feet till the rock is reached. In many cases surface oil is found before reaching the rock, but it is of rather inferior quality and doubtful yield. After arriving at the rock, the wells through the earth being from 4 to 7 feet square, they drill to a depth of from 40 to 70 feet, between which distances oil is almost sure to be discovered. Wooden tanks, varying from 500 to 2,000 gallons capacity, are constructed close to each well. The oil is pumped into these, and afterwards drawn off into barrels to be sent to market. The cost of a well is very small. Parties are in the district making contracts for sinking wells. Their charge is, for sinking through the earth 2½ dols. per foot, and for drilling through the rock 2½ dols. per foot. A well after being commenced usually yields oil in less than 30 days. At these prices a well can be sunk, a tank for 100 gallons made, and a pump and all necessary appliances provided for a sum equal to about 100l. sterling. When oil is found, one man at 4s. a day can readily pump 100 barrels, or 4,000 gallons a day. The cost of the oil, including every expense, and calculating the reimbursement of every outlay incurred in one year, and also calculating a yield of 15 barrels, or 600 gallons, a day, is, it is alleged, absolutely less than a half-penny sterling a gallon delivered into the tank alongside the well. Very few attempts have yet been made to pump by steam at the place where the oil is most extensively found, nearly all the labour being by hand. This is partly to be attributed to the badness of the roads, preventing the possibility of getting heavy loads into the district, and partly to the yield of the wells being on an average about equal to the quantity a man can easily pump in a day. A moderate average yield for all the wells now in operation (100) is 15 barrels, or 600 gallons, a day. At the rate at which privileges are being disposed of and parties are preparing to sink wells, there will be 500 in operation before Christmas. Taking the present 100 wells only, however, the result is extraordinary. Thus—100 wells yielding 600 gallons give 60,000 gallons per day, 360,000 per week, or 18,720,000 per annum. A trustworthy observer remarks:—"Such a yield seems almost fabulous, and yet I believe, from personal observation and enquiry on the spot, that it is within the truth."

Diamonds.—In the official statistical report of the value of produce exported from Bahia, Brazil, an amount is included not exceeding 150,000l., whereas an amount superior to 500,000l., worth of this precious stone is clandestinely sent out of the country yearly. The discovery of the diamond mines in the district of Paraguassú, in the year 1845, has effected great and beneficial results to the population and commerce. What was in that year but a desert, is now one of the most flourishing districts, inhabited by a laborious and daily-increasing population. The town of Isabel de Paraguassú and neighbourhood contains 60,000 souls; that of Lencóas, 30,000; and Andarahy, 20,000—all the result of this discovery; and it may truly be said that those mines have realised for the poorer population of the interior, the same good we have

observed in California and Australia. It has opened a large field to all without dependence on professional skill or capital, of which the majority were not possessed; and in a moral sense has operated wonders in reclaiming the vicious from habits of indolence and crime. These men, finding in the extraction of diamonds an advantageous profit, naturally became large consumers of the produce of the country, which, for the want of market, was not cultivated; and altering their habits of life, increased their well-being, and eventually made them consumers of the produce of foreign countries. The town of St. Isabel de Paraguassú is now the chief depôt of the trade of the north-west of this province, and supplies all the interior populations with the comforts of European civilisation, a population calculated at no less than 700,000 souls. In the neighbourhood of St. Isabel the cotton plant flourishes, and nitrate of soda is found—but the great difficulty to the exportation of these valuable products is the want of a good road to this port. Last year I used all my influence and endeavours with the late President to promote the passing of a law in the Assembly, guaranteeing five per cent. on the capital expended in the construction of a good carriage road. The law was passed and duly sanctioned by the late President, but, unfortunately, that law has been revoked. To give an idea of the importance of the road in question, it is enough to state that goods (foreign) to the value of 600,000l. to 1,000,000l. sterling are annually sent to the diamond district from this city, and that its exports in diamonds average between 600,000l. to 800,000l. per annum; no calculation being possible of the value of cotton, nitrate of soda, hides, skins, cattle, iron, &c., &c., that would be sent down, had the road I had so strongly recommended been carried into execution.—*Extract from the Report of H. B. M. Consul.*

ANSWERS TO CORRESPONDENTS.

Kafes and Adolphe.—Received.

J. S. Blockey.—Your suggestion is received with thanks, and will be attended to if practicable.

Applied Chemistry, by M. Barrowwill.—Will the correspondent who last week left at our office a short paper with the above heading, favour us with the second part?

Tri-ethyl phosphine.—A correspondent wishes to be informed of the best method of preparing this new reagent for bisulphide of carbon in coal gas.

T. King.—1. Professor Johnstone has written an excellent little work on "The Analysis of Soils and Manures," and we believe Mr. Nesbit, of Kennington, has also published a similar volume. 2. At the Government School of Mines, Jermyn Street, or at Chapman and Hall's.

Brvata.—In the article "Researches on the Assay of Silver," in our last No., p. 125, fourth line, for "double salt KO +," read "SO₄KO +." The last three lines (in p. 127) should read thus:—"A little chlorine soon prohibits its further formation. This, also, is an interesting instance of the influence of quantity on chemical affinity."

Ventilation.—A correspondent has drawn our attention to the subjoined extract from the *Scientific American* of the 21st ult.:—"An English journal says that 'the new system of ventilation, patented by the National Ventilation Company, consists in a nice adaptation of wire-gauze to open windows, so that the air is allowed to steal gently on and out, while violent draughts, and those enemies to ventilation, the blacks, are excluded.' We should like to know what on earth is new about this mode of ventilation that it should attract the attention of the National Ventilation Company. The same thing is in extensive use in this country, and has been for years—used for the double purpose of ventilation and to keep out noxious insects."

Nitro-Prusside of Sodium.—*Theophilus.*—This reagent is prepared by treating 2 parts of powdered ferrocyanide of potassium with 5 parts of common nitric acid previously diluted with its own volume of water. The solution, after the evolution of gas has ceased, is digested on the water-bath until salts of protoxide of iron no longer yield a blue but a slate-coloured precipitate. The liquid is now allowed to cool, when much nitrate of potash and occasionally oxamide is deposited; it is filtered and neutralised with carbonate of soda which yields a green or brown precipitate and furnishes a ruby-coloured filtrate. This, on evaporation, gives a crystallization of nitrate of potash and soda together with the new salt. The crystals of the latter are selected and purified by crystallization; they are rhombic, and of a splendid ruby colour.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Transformation of Monobromated Propylene into a New Hydrocarbide of the Composition, C_3H_4 , by M. SAWITSCH.

In a paper on the preparation of acetylene by bromated ethylene, I ventured the opinion that by applying the same method to the superior homologues of this body, the series of hydrocarbides C_nH_{2n-2} would be obtained. Experience has fully confirmed my opinions, at least in that which concerns the second part of the series. In fact, by submitting monobromated propylene to the action of soda alcohols, one equivalent of hydrobromic acid may be taken away, transforming it into a carbide, C_3H_4 , to which I have given the name of *allylene*.¹

The details of the operation are identical with those I have already pointed out with respect to acetylene, with this difference, that ethylate was substituted for acetylate of soda. When the balloon, previously cooled, in which the reaction took place was opened, a considerable quantity of a gaseous mixture was disengaged,² which was several times passed through a solution of ammoniacal oxide of copper, in which it deposited a large, flaky, canary-yellow precipitate, possessing the following properties:—Heated, it decomposes with deflagration and the production of a reddish flame; thrown into bromine, it is destroyed, occasioning a rustling sound, accompanied by a red flame; finally, cold, concentrated acids immediately disengage gas from it, which is set free under the influence of diluted acid, particularly of hydrochloric acid, but only by the application of heat.

This last reaction is utilised in the preparation of pure allylene. This gas is colourless, with a strong and disagreeable odour, though less so than that of acetylene. It burns with a brilliant, fuliginous flame. It precipitates mercurous and argentine solutions,—the former dark gray, the latter white. These two combinations having a composition probably analogous to cuprous compounds, are, like them, unstable; they decompose by heat, the former without detonation, the latter with an explosion and a reddish flame.

The endiometric analysis of the gas gives the following results:—

Temperature . . .	13°
Barometer . . .	0.763m'
Volume of gas . . .	2.69 c. c.
Volume of oxygen added .	21.92 "
Total volume . . .	24.61 "
After . . .	19.10 "
After potassa . . .	11.02 "

¹ This name was previously proposed by M. Berthelot in his work on Organic Chemistry, vol. II., p. 161.

² Twenty-five grammes of monobromated propylene have yielded about three litres of gas. To extract the whole, the balloon must be gradually heated to the boiling point of alcohol, in which allylene is soluble.

	Experiment.	Theory.
	c. c.	c. c.
Disappeared . . .	5.51	5.38
Carbonic acid formed .	8.08	8.07
Oxygen consumed . .	10.90	10.76

or, by comparing the results of experiment with one volume of gas:—

Contraction . . .	2.04	2.00
Carbonic acid . . .	3.00	3.00
Oxygen consumed . .	4.05	4.00

I had not sufficient gas at my disposal to enable me to determine its density, and thus to corroborate the formula, $C_3H_4 = 2$ vols., which, nevertheless, seems to me incontestable, looking to the mode of formation of this body, to its composition, and to the similarity of its properties with those of acetylene, respecting whose formula no doubt can be entertained. The curious property of precipitating ammoniacal solutions of copper, which has enabled me to isolate allylene, seems to be characteristic of the hydrocarbides of this series, at least, judging from the two first terms. There is good reason to believe that it will lead to the discovery of higher terms.

I propose soon to return to the study of the physical and chemical properties of allylene and its derivatives. At present I confine myself to the mention of bromide of allylene, a limpid and colourless liquid, smelling like tribromide of allyle, and which I obtained by dropping allylene into bromine.

It may not be needless to remark, that, in order to obtain every desirable guarantee of the purity of the gas, I employed monobromated propylene, prepared by means of propylene gas, proceeding from the reduction of iodide of allyle by mercury and hydrochloric acid. In my opinion, this is the only way to obtain pure bromated propylene.

These researches were made in M. Wurtz's laboratory. — *Comptes-Rendus*.

On the Presence of Nitrates in Mineral Waters, and on the Production of Saltpetre, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

In September, 1851, the Medical Board sent me for analysis five bottles of well-water from Aden, each from a different well. These waters were all clear and colourless, neutral to test-paper, and of a more or less bitter, nauseous, saline taste, like a dilute solution of Epsom salts.

The analysis was conducted in the usual way; but from the small quantity of each water available, it was necessary to economise the supply as much as possible, and any attempt to estimate the less abundant constituents, as bromine, iodine, fluorine, &c., was out of the question.
